Our results have implications for the bottom culture of scallops, and suggest that aquaculturists should carefully consider the sea bottom characteristics of the site before seeding scallops. Juvenile scallops select more heterogeneous sediment types (e.g., granule or pebble) over more homogeneous substrates (sand or flat, hard bottoms). Therefore, dispersal of scallops away from a site will be higher on less suitable sediment types. This has been observed in early seeding trials off the Magdalen Islands, Quebec, Canada, where sea scallops were released on sand (Picard & Vigneau 1992). Dispersal from certain sediment types has been observed in other scallop species, such as bay scallops (*Argopecten irradians*), which swim from an unnatural sediment (sand) to their normal substrate (eelgrass blades) (Winter & Hamilton 1985), and great scallops (*Pecten maximus*), which have a higher probability of swimming from bedrock than from sediments suitable for recessing (Baird 1958, Baird 1966). Furthermore, in our system, sea scallop dispersal will be higher if sea stars are present, because sea star encounter seems to be a primary trigger for scallop swimming. Encounter with crab predators may also trigger swimming of sea scallops, but not to the extent of encounters with sea stars. Note, however, that crabs can be much more effective scallop predators than sea stars (Barbeau & Scheibling 1994). Based on research with another scallop species (Talman et al. 2004), the foraging efficiency of both predator types may be reduced in habitats with high structural complexity (e.g., high density of macrophytes). Additionally, the sediment type of an aquaculture site should be considered in terms of scallop growth. Brand (1991) reported faster growth of various scallop species (e.g., *P. magellanicus*, *A. irradians*, *P. maximus*) on sediments with little silt or mud. Thus, seeding sea scallops onto sediments with large particle sizes may lead to faster growth. Generally, sediment type remains an impor-

tant factor that can influence the success of bottom culture operations by affecting predator-prey interactions, scallop movement, and scallop growth.

EFFECT OF MICROALGAL CONCENTRATION AND WATER TEMPERATURE ON THE PHYSIOLOGY OF THE CARIBBEAN SCALLOPS *ARGOPECTEN NUCLEUS* AND *NODIPECTEN NODOSUS*

L. A. VELASCO*

Instituto de Investigaciones Tropicales (INTROPIC), Universidad del Magdalena, Carrera 2 No 18-27, Taganga, Santa Marta, Colombia

ABSTRACT *Argopecten nucleus* and *Nodipecten nodosus* are two Caribbean scallops occurring in Colombia, which have recently been selected for artificial culture based on their high commercial value. As part of an effort to develop culture technology for these species, we studied the effects of food concentration and temperature on feeding rates (filtration, ingestion, and absorption), oxygen consumption, ammonium excretion and scope for growth in adults of the two scallop species. We tested the effects of four concentrations of the microalga *Isochrysis galbana* (10, 20, 40 and 60 cells μL^{-1}) at three water temperatures (20, 25 and 28°C), at a constant salinity of 36‰. The results showed that increases in food concentration induced increases in feeding rate, oxygen consumption and growth potential, but at values of 60 cells μL^{-1} these variables decreased, indicating saturation of the digestive tract. The excretion rate increased at low food concentrations, particularly at the middle (25°C) and/or at the highest temperature tested (28°C). This suggested utilization of endogenous proteins as a supplementary energy source under these conditions. The increase in temperature had no significant effect on the feeding variables or on the scope for growth of *A. nucleus*, but raised the *N. nodosus* ones. All the physiological rates for the two species were similar except for oxygen consumption, which was greater in *N. nodosus* than in *A. nucleus*. Using values obtained for the algae concentrations, which produced the greatest growth potential, the optimal value for *I. galbana* for both the scallops was 40 cells μL^{-1} , whereas the optimal temperature for *N. nodosus* was 25°C. There was no single optimal temperature for *A. nucleus*, which functioned equally well at between 20°C and 28°C.

KEY WORDS: scallop physiology, scallop culture, *Argopecten nucleus*, *Nodipecten nodosus*, Colombia, Caribbean.

INTRODUCTION

Temperature and concentration of particulate food are two of the main factors that affect bivalve filter feeders in relation to their growth (Wilson 1987), survival (Paul 1980), gonadal conditioning (Martínez et al. 2000, Martínez & Pérez, 2003) and physiology (Bricelj, et al. 1987, Navarro & Iglesias 1995, Navarro et al. 2000). Studies carried out on the physiology of bivalve filter feeders in response to broad ranges of microalgal concentrations (Griffiths & King 1979, Bacon et al. 1998, MacDonald et al. 1998, Velasco & Navarro 2002, 2003) and/or water temperature (Alí 1970, Winter 1970, Bougrier et al. 1995, Sicard et al. 1999, Laing 2000) have shown that the filtration rates, ingestion, absorption, oxygen consumption and/or excretion become modified with changes in these parameters, and allow maintenance of high values in scope for growth within given ranges of the parameters depending on the species observed.

Argopecten nucleus (Born, 1780) and *Nodipecten nodosus* (Linné, 1758) are two scallops of commercial importance from the Caribbean coast of Colombia. These species are epibenthic filter feeders and may coexist on sandy bottoms from 10–100 m depth. *A. nucleus* is a moderately-sized, unattached species (length = 50 mm), whereas *N. nodosus* is a larger (length = 150 mm) species, which remains attached to hard substrates. No naturally occurring beds of these scallops have been encountered in the sea off Colombia; population aggregates have been maintained in artificial cultures, produced from the capture of (scarce) naturally occurring seed obtained in spat collectors (maximal of 6–77 spats collector⁻¹) (Urban, 1999). These two scallop species have shown high growth rates in suspended cultures, reaching commercial sizes within 11 mo (Urban 1999, INVEMAR 2003). It is known that growth and survival of *N. nodosus* is negatively affected by ex-

treme temperatures (<20°C and >29°C), low salinities (<29‰) and high turbidity (Rupp & Parsons 2004, Rupp et al. 2005).

Because the scarce availability of wild “seed” does not support commercial cultures of these scallops, it was of interest to develop the technology for seed production under hatchery conditions. Success in seed production depends on the identification of optimal environmental parameters for maintenance of the adults, larvae and postlarvae in the laboratory. Because the two species under study occur naturally in relatively high and constant salinity, whereas the temperature and environmental food offerings may vary considerably, we selected the latter two variables of interest for the present study. In preliminary studies we determined that the chrysophyte *Isochrysis galbana* produced the best scope for growth in the two scallop species (Velasco, in press). This study was carried out to determine the effect of different concentrations of *I. galbana* and different temperatures on physiological variables related to feeding (filtration rates, ingestion and absorption), oxygen consumption, excretion and scope for growth of *Argopecten nucleus* and *Nodipecten nodosus* adults.

MATERIALS AND METHODS

Collection and Maintenance of Scallops

Specimens of *Argopecten nucleus* (mean length 47 ± 5.3 mm and dry weight 1.25 ± 0.35 g) and *Nodipecten nodosus* (mean length 71 ± 9.5 mm and dry weight 2.26 ± 0.85 g) were collected at the Bahía Neguanje bivalve culture station (Lat. 11° 20' N., Long. 74.05° W.), in Santa Marta, Colombia. The water temperature in this area ranges between about 22°C and 30°C, with salinities between 33 and 37 ‰ and environmental seston concentrations between 0.2 and 4.7 mg L⁻¹; the organic content of the seston ranged between 15% and 60% (Urban 1999).

The scallops were transported wet, at a temperature similar to that of the environment, to the Mollusc and Microalgae Laboratory

*E-mail: luza.velasco@unimagdalena.edu.co

of the Universidad del Magdalena at Taganga (Lat. 11°16'N, Long. 74°11'W), where they were cleaned of epibionts, and individually marked. Acclimation to laboratory tanks was achieved by maintaining the scallops for one week in static seawater in a 250 L tank at a salinity of 36 ‰ and temperature of 25°C. The water was aerated with a compressed air bubbler, and a daily food ration of *Isochrysis galbana* equivalent to 3% of the dry weight of the scallops. The water was renewed every 24 h.

Experimental Design

A factorial design was used in which physiological parameters of the scallops were measured at three different water temperatures (20, 25°C, and 28°C) and four different feeding regimes with *Isochrysis galbana* at 2, 4, 8 and 12 mg L⁻¹ (10, 20, 40 and 60 cells µL⁻¹ respectively). Each of these 12 treatments was applied to seven individual scallops of each species selected haphazardly from the original groups of specimens obtained. The salinity was maintained at 36‰ in all the experiments; complete oxygen saturation was maintained in the water over a period of 15 h, of which 12 h represented an acclimation period in the test system with a three hour period for taking the measurements.

The experimental diets were administered using a flow-through system consisting of 16 chambers (0.8 L for *A. nucleus* and 1.6 L for *N. nodosus*), designed following Riisgård (1977). A constant flow (150 ± 10 mL min⁻¹) of the experimental diet was directed by gravity from a mixing tank into each chamber; 14 chambers were used for individual bivalves (7 individuals of each species) and 2 chambers contained empty valves, which served as controls. Normal valve opening by test specimens was monitored and individuals that failed to open normally were eliminated from the experiment.

The experimental diets were prepared by mixing appropriate volumes of 1-µm microfiltered seawater and the microalgae *Isochrysis galbana*, which had been cultured in F/2 medium (Guillard 1974), after direct cell counts of cell densities by hemacytometer.

Characterization of Feeding Ration

Each experimental diet was analyzed in terms of total particulate matter (TPM) and particulate organic matter (POM). Water was sampled from the outflow of both control chambers every hour. Each sample was divided into three subsamples, which were filtered onto tared Millipore glass fiber filters (α = 0.45 µm), which had been prewashed in distilled water and preashed at 450°C for 4 h. Filters with samples were rinsed with isotonic ammonium formate to remove salt and prevent cell lysis, and were dried at 70°C for 48 h to determine the TPM (mg L⁻¹). POM (mg L⁻¹) was determined as the loss in weight of the samples after ashing at 450°C for 4 h.

Determination of Physiological Feeding Variables

These variables were determined by the method of biodeposition described by Iglesias et al. (1998), as validated by Navarro and Velasco (2003) using the flow-through chamber method described by Riisgård (2001). Feces and pseudofeces were quantitatively collected every 3 h using Pasteur pipettes. The mass and organic content of the material deposited by each test bivalve were estimated separately using the method described above for the diet analysis. The equations for the physiological variables were the same as those of Iglesias et al. (1998).

Filtration Rate

Filtration rate (FR) represents the amount of particulate material removed from the water per unit time.

$$\text{Inorganic filtration rate} \quad \text{IFR (mg h}^{-1}\text{)} = \text{IRR} + \text{IER} \quad (1)$$

$$\text{Organic filtration rate} \quad \text{OFR (mg h}^{-1}\text{)} = \text{IFR} * (\text{POM/PIM}) \quad (2)$$

$$\text{Total filtration rate} \quad \text{FR (mg h}^{-1}\text{)} = \text{IFR} + \text{OFR} \quad (3)$$

where: *IFR* = inorganic filtration rate (mg h⁻¹); *IRR* = rate of production of pseudofeces inorganic matter (mg h⁻¹), *IER* = rate of production of feces inorganic matter (mg h⁻¹), *POM* = particulate organic matter (mg L⁻¹) and *PIM* = particulate inorganic matter (mg L⁻¹).

Ingestion Rate

When no pseudofeces is produced the total filtration and organic matter filtration rates are represented, respectively, by the total (IR) ingestion rate and organic ingestion rates (OIR). When pseudofeces is produced, the IR is calculated by subtraction of the rate of pseudofeces production from the FR (Bayne et al. 1993).

$$\text{IR (mg h}^{-1}\text{)} = \text{FR} - \text{RR} \quad \text{OIR (mg h}^{-1}\text{)} = \text{OFR} - \text{ORR} \quad (4)$$

where: *RR* = rate of production of total pseudofeces (mg h⁻¹) and *ORR* = rate of production of pseudofeces organic matter (mg h⁻¹).

Efficiency (AE) and rate of absorption (AR): represent material ingested, which is absorbed per unit time.

$$\text{AE}(\%) = \text{AR}/(\text{OFR} - \text{ORR}) * 100 \quad (5)$$

$$\text{AR (mg h}^{-1}\text{)} = \text{OIR} - \text{OER} \quad (6)$$

where: *OER* = rate of production of feces organic matter (mg h⁻¹).

Oxygen consumption (CO: mL O₂ h⁻¹) and ammonia excretion (UR: µg NH₃-N h⁻¹): were determined on fed animals by placing them in individual chambers (0.8 and 3 L) after rinsing the chambers with 25% HCl and filling with <1-µm filtered seawater. Chambers were sealed and incubated for 2 h at the same temperature in which they have been fed, alongside a control chamber devoid of specimens. Two water samples were then taken from each experimental chamber to determine oxygen consumption rates and rates of excretion. Oxygen consumption was never measured at ambient oxygen tension lower than 70% saturation. Oxygen concentration was estimated by the Winkler method, modified after Carritt and Carpenter (Strickland & Parsons 1972) and ammonia excretion was determined by the phenol-hypochlorite method (Solorzano 1969).

Scope for growth (SFG): is a physiological index of energy balance to estimate production (growth + reproduction) by an individual animal. It was calculated from the equation given by Widdows (1985) after converting all the physiological rates to energy equivalents (J h⁻¹):

$$\text{SFG} = \text{A} - (\text{R} + \text{U}) \quad (7)$$

where: *A* = Energy absorbed (J h⁻¹) = *AR* mg h⁻¹ × 11.40 J mg⁻¹ (Velasco, in press), *R* = Oxygen consumption (J h⁻¹) = *OC* mL O₂ h⁻¹ × 20.08 J (Gnaiger 1983), *U* = Ammonia excretion (J h⁻¹) = *UR* mg NH₃-N h⁻¹ × 24.8 J (Elliot & Davison 1975).

Standardization of Variables

The physiological rates were converted to a standard individual of 1-g dry tissue weight and with a macroscopic gonadal stage of I; for this, the soft tissues were dried at 70°C for 48 h, and then individually weighed. Standardization used the equation of Bayne et al. (1987).

$$Y_{ts} = (1 \text{ g}/W_e)^{b1} \times Y_e \quad (8)$$

$$Y_{ms} = (1/E)^{b2} \times Y_{ts} \quad (9)$$

where Y_{ts} = physiological rate of an individual of standard size (1 g), Y_e = uncorrected rate, W_e = weight of the experimental individual, $b1$ = dependence of the physiological rates on the sizes of the individuals, Y_{ms} = physiological rate of the individual at a standard stage of maturity (I), E = stage of maturity of the experimental individual (between I and 4) and $b2$ = dependence of the physiological rates on the stage of maturity of the individuals. The "b" values used for each physiological rate were determined from exponential regressions between the physiological measurements, the dry weights, and stage of maturity of specimens of different sizes and degrees of maturity of the two scallop species. For the rate of production of biodeposits, the $b1$ values were 0.98 and 0.41 and for $b2$ they were -0.67 and -0.44 for *Argopecten nucleus* and *Nodipecten nodosus*, respectively. For the oxygen consumption rates, the $b1$ values were 1.52 and 0.43 and for $b2$ they were 0.32 and 0.52 for *A. nucleus* and *N. nodosus*, respectively. Finally, for the rates of excretion, the $b1$ values were 1.16 and 0.97 for *A. nucleus* and *N. nodosus*, respectively, and no standardization was carried out related to the stage of maturity, because this factor did not affect the excretion rate.

Statistical Analyses

Tests were carried out on the normality and the homogeneity of the variances of all the physiological variables, and transformed to comply with these requisites. Clearance, filtration, ingestion, absorption and SFG were transformed to square, oxygen consumption was transformed to square roots, and a rank transformation was applied to the absorption efficiency and excretion rate data. Factorial analyses of variance were carried out to establish the degree of influence of the food concentration and temperature, and the interactions of these two factors on each of the physiological variables. One-way analyses of variance were carried out to make specific comparisons between treatments, and to determine significant differences among them using a Bonferroni multiple range test. Correlation analyses were carried out to establish associations among the physiological variables. Finally, analyses of covariance were carried out to compare the physiological variables between the two species. All the statistical analyses were carried out using Statgraphics-plus 5.0 software, with an α of 0.05 for all tests of significance.

RESULTS

Feeding Rates

The highest rates of filtration, ingestion and absorption by *Argopecten nucleus* were 85.2, 55.5 and 52.4 mg h⁻¹, respectively, whereas the lowest rates, respectively, were 7.1, 4.6 and 4.1 mg h⁻¹. In *Nodipecten nodosus* the filtration rates varied between 5.8 and 83.5 mg h⁻¹; ingestion rates between 3.7 and 56.7 mg h⁻¹ and the absorption rates between 3.2 and 53.3 mg h⁻¹ (Fig. 1). The

food concentration significantly affected the rates of filtration, ingestion and absorption of *A. nucleus* (df = 3, $P < 0.001$) and *N. nodosus* (df = 3, $P < 0.0001$). Increase in physiological rates occurred with increases in the food concentration, with the highest values observed at 40 cells μL^{-1} . At food concentrations of 60 cells μL^{-1} all the rates decreased, except in *N. nodosus* at 20°C, where they continued to increase.

Temperature did not significantly affect the feeding rates of *Argopecten nucleus* (df = 2, $F = 1.13$, $P = 0.3316$) whereas the contrary was true of *Nodipecten nodosus* (df = 2, $F = 22.22$, $P = 0.0001$), although only when the scallops were presented with intermediate food concentrations (20 and 40 cells μL^{-1}); at these food concentrations, the low temperature (20°C) and the high temperature (28°C) produced a significant decrease in the physiological variables related to feeding. The analysis of covariance showed that the feeding rates of both scallop species were statistically similar (df = 1, $P < 0.0828$). There was production of pseudofeces in all the treatments; in *N. nodosus* this varied between 14% and 52% of the material filtered, whereas in *A. nucleus* this range was between 18% and 47%, with the highest values observed in the treatments containing the highest food concentrations and at extremes of temperature.

Absorption Efficiency

The absorption efficiency of *Argopecten nucleus* varied between 60.9% and 96.3%, whereas that of *Nodipecten nodosus* was between 74.5% and 97.5% (Fig. 2). The concentration of microalgae had a statistically significant influence on the absorption efficiency of both scallop species (df = 3, $P < 0.0020$), but a direct relation was not verified. The values obtained at 40 cells μL^{-1} were significantly higher than those at 20 cells μL^{-1} . Temperature affected the efficiency of absorption of *A. nucleus* (df = 2, $F = 6.33$, $P = 0.0034$), with higher values obtained at 25°C than at the other temperatures. In *N. nodosus* the absorption efficiency was not significantly affected by the temperature (df = 2, $F = 2.83$, $P = 0.0666$). The analysis of variance did not detect significant differences between the absorption efficiencies of the two species (df = 1, $F = 0.01$, $P = 0.8289$).

Oxygen Consumption Rate

The oxygen consumption of *Argopecten nucleus* varied between 0.18 and 1.05 mL O₂ h⁻¹ and that of *Nodipecten nodosus* was between 0.5 and 1.63 mL O₂ h⁻¹ (Fig. 3A). The factorial analysis showed that the oxygen consumption by the scallops was significantly affected by the food concentration (df = 3, $P < 0.0001$) and temperature (df = 2, $P < 0.0001$). In *A. nucleus* the oxygen consumption rates were significantly lower at the lowest algal concentration (10 cells μL^{-1}), whereas in *N. nodosus* the highest values were obtained at 40 cells μL^{-1} . Increase in temperature increased oxygen consumption, with statistically higher values at 25°C and 28°C in *A. nucleus* and at 28°C in *N. nodosus*. The analysis of covariance showed that the oxygen consumption by *N. nodosus* was significantly higher than that of *A. nucleus* (df = 1, $F = 35.13$, $P = 0.0001$).

Excretion Rate

Ammonium production by *Argopecten nucleus* varied between 91.9 and 326.6 $\mu\text{g h}^{-1}$, whereas that of *Nodipecten nodosus* ranged from 84.2–340.4 $\mu\text{g h}^{-1}$ (Fig. 3B). The factorial analysis of variance showed that the rate of excretion by the two scallop species

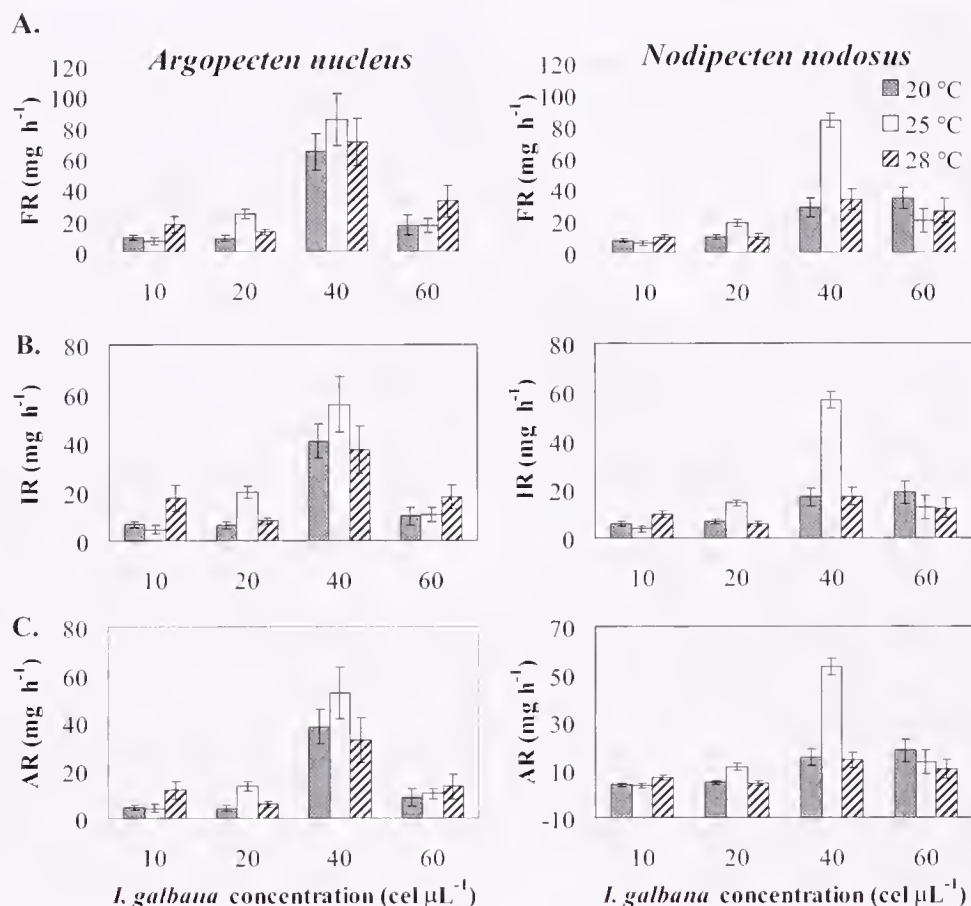

Figure 1. *Argopecten nucleus* and *Nodipecten nodosus*. Feeding rates under different concentrations of *Isochrysis galbana* and water temperatures. A. Filtration rates, B. ingestion rates and C. Absorption rates.

was significantly affected by the microalgal concentration ($df = 3$, $P < 0.0016$) and by the water temperature ($df = 2$, $P < 0.0030$). The excretion rates measured at the lowest food concentration (10 cells μL^{-1}) were significantly higher than those obtained at higher food concentrations (40 cells μL^{-1}). The temperature affected the excretion rate of these scallops only at low food concentrations (10 and 20 cells μL^{-1}), and produced significantly higher values at 25°C than at 20°C ($df = 2$, $P < 0.0300$). At higher food concentrations, the excretion rate was not influenced by temperature ($df = 2$, $P > 0.1275$). No statistical differences were detected between the rates of ammonium release by the two scallop species ($df = 1$, $F = 0.08$, $P = 0.7841$) using the analysis of covariance.

Scope for Growth

The scope for growth of *Argopecten nucleus* fluctuated between 33.2 and 580.2 J h^{-1} and that of *Nodipecten nodosus* between 9.6 and 582.2 J h^{-1} (Fig. 4). The correlation analysis showed a positive association between the scope for growth and the feeding variables, which was highly significant ($r > 0.9784$, $P < 0.0001$), whereas no association was noted between the oxygen consumption rates ($r = -0.08$, $P = 0.3579$). Correlation of the scope for growth with excretion rates was negative ($r = -0.2422$, $P = 0.005$). The factorial analysis of variance showed that the growth potentials of the two scallops was significantly influenced

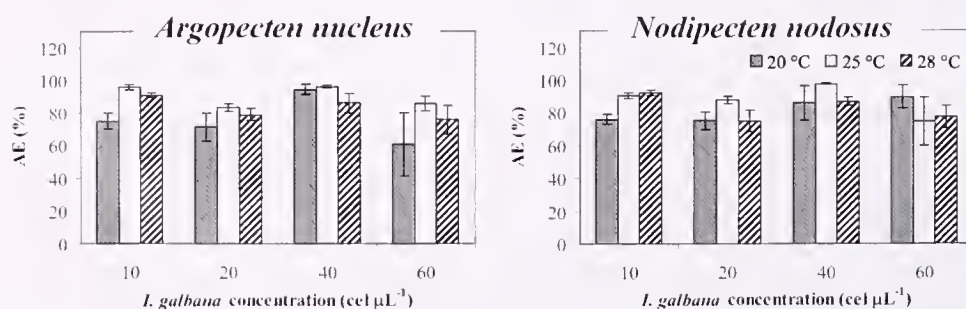

Figure 2. *Argopecten nucleus* and *Nodipecten nodosus*. Absorption efficiencies under different concentrations of *Isochrysis galbana* and water temperatures.

Figure 3. *Argopecten nucleus* and *Nodipecten nodosus*. A. Oxygen consumption rates and B. Ammonia excretion rates under different concentrations of *Isochrysis galbana* and water temperatures.

by the microalgal concentration ($\text{df} = 3$, $P < 0.0001$), whereas the water temperature affected *N. nodosus* ($\text{df} = 2$, $F = 16.01$, $P = 0.0001$) and not *A. nucleus* ($\text{df} = 2$, $F = 0.86$, $P = 0.4289$). The scope for growth increased together with food concentration up to 40 cells μL^{-1} and thereafter decreased at 60 cells μL^{-1} , except in *N. nodosus* at the low temperature (20°C), at which the scope for growth continued to increase. Temperature affected the scope for growth of *N. nodosus* only at the intermediate food concentrations of 20 y 40 cells μL^{-1} ($\text{df} = 3$, $P < 0.0277$), with an increase in scope for growth stimulated at 25°C. The analysis of covariance showed that the scope for growth of the two scallops was statistically similar ($\text{df} = 1$, $F = 3.2$, $P = 0.0761$).

DISCUSSION

Feeding Rates

The highest rates of filtration, ingestion, and absorption recorded for the two scallop species in this study were obtained at intermediate concentrations of microalgae offered as food. These results were in agreement with results of previous studies on the feeding of bivalves exposed to broad ranges of algal concentration

as in the case of *Mytilus chilensis* (Velasco & Navarro 2002, 2003). The decrease in feeding rates at high concentrations of microalgae has not been noted in other studies, such as those of *Anulcomya ater* (Griffiths & King 1979), *Mytilus chilensis* (Navarro & Winter 1982), *Placopecten magellanicus* (Bacon et al. 1998) and *Musculista senhousia* (Inoue & Yamamuro 2000). Alternatively, stabilization of feeding rates may occur at high food concentrations, as shown for *Tapes philippinarum* (Coutteau et al. 1994); *Mya arenaria* (Bacon et al. 1998) and *Mulinia edulis* (Velasco & Navarro 2002, 2003). It may be that the latter two results were because of the narrow range of microalgal concentrations tested. The reduced feeding rates of the bivalves at low food concentrations has been explained as the direct, and uncontrolled scarcity of food, whereas at high concentrations it may represent a reduction in the pumping of water, and to the increase in production of pseudofeces, which allows the bivalve to regulate the ingestion rate and avoid saturation of the alimentary system (Iglesias et al. 1996, Velasco & Navarro 2002). The concentration of *Isochrysis galbana* at which the ingestion rate of *Argopecten nucleus* and *Nodipecten nodosus* was at a maximum, inducing regulation, or lowering of ingestion ("saturation concentration"), was at 40 cells μL^{-1} (8 mg L^{-1}); this value coincided with that observed in other bivalves fed on microalgal diets including *Meretrix meretrix*

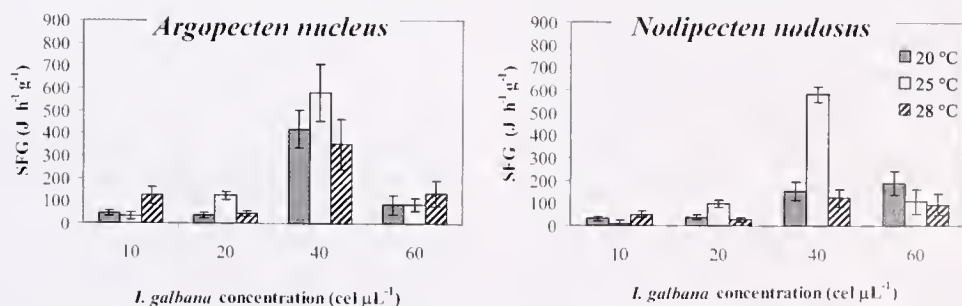

Figure 4. *Argopecten nucleus* and *Nodipecten nodosus*. Scope for growth under different concentrations of *Isochrysis galbana* and water temperatures.

(8 mg L⁻¹, Zhuang & Wang 2004) and *P. magellanicus* (7 mg L⁻¹, Bacon et al. 1998).

The lack of influence of the temperature on the feeding rates of *Argopecten nucleus* showed that this species had a high capacity for rapid acclimation within the temperature range tested. Similar results had previously been presented for *Argopecten purpuratus* exposed to 16°C and 20°C for three weeks (Navarro et al. 2000). The increase in feeding rates in *Nodipecten nodosus* with increase in temperature and its decrease at temperatures as high as 28°C, indicated that this species did not become acclimated to different temperatures in a short time (15 h). This result coincided with the responses described for other bivalves, including *Argopecten ventricosus* (Sicard et al. 1999) and *Pecten maximus* (Laing 2000). Other studies only described increases in feeding rates with increases in temperature, as with *Arctica islandica*, *Modiolus modiolus* (Winter 1970), *Venerupis decussata*, *Mercenaria mercenaria* (Walne 1972), *Ostrea edulis* (Beiras et al. 1995) and *Pecten fumatus* (Heasman et al. 1996) possibly because of the fact that the cited authors worked within a narrower temperature range. The presently described effect of temperature on the feeding rates of *N. nodosus* was observed only at intermediate food concentrations (20 and 40 cells μ L⁻¹). Extreme concentrations apparently produce a limiting effect, which annulled the positive effect obtained at intermediate temperature (25°C).

The similarity between feeding rates in *Argopecten nucleus* and *Nodipecten nodosus* contrast with the higher capacity for retaining particulate in the bigger branchial area per unit dry weight of *N. nodosus* (Velasco, in press). It suggests that *A. nucleus* has higher pump activity than *N. nodosus*. Other studies, which have compared interspecific feeding rates have demonstrated greater particle retention and feeding rates in species having greater branchial surface areas (Foster-Smith 1976, Hawkins et al. 1990, Velasco & Navarro 2002).

Absorption Efficiency

Absorption efficiency generally decreases when the concentration of microalgae increases, as in the cases of *Mytilus edulis* (Widdows 1978), *Aulacomya ater* (Griffiths & King 1979), *Mytilus chilensis* (Navarro & Winter 1982), *Argopecten purpuratus* (Fernández-Reiriz et al. 2005) and *Hiattella arctica* (Sejr et al. 2004). This has been attributed to the decrease in residence time of the food in the stomach when the ingestion rate is high (Bayne et al. 1989). The absorption efficiencies of *Argopecten nucleus* and *Nodipecten nodosus* were relatively high, and its variation showed no relation with the concentration of microalgae, nor with the ingestion rate, in agreement with the results obtained with *Mya arenaria*, *Placopecten magellanicus* (MacDonald et al. 1998) and in *Meretrix meretrix* (Zhuang & Wang 2004). The maintenance of high absorption efficiencies in *A. nucleus* and *N. nodosus* at the highest food concentration tested could be related to the strong regulation of the ingestion rate, which avoids oversaturation of the digestive tract and affects the efficiency of the digestive process.

The lack of influence of temperature on the absorption efficiency of *Nodipecten nodosus* coincides with that found for *Argopecten purpuratus* after an acclimation period (Navarro et al. 2000), indicating a high degree of plasticity in this variable with regard to temperature changes. In *Argopecten nucleus* the increase in temperature from 20°C to 25°C produced an increase in the absorption efficiency as noted for *Ostrea edulis* (Beiras et al. 1995) and *Meretrix meretrix* (Zhuang & Wang 2004). Low temperatures

produce a decrease in kinetic energy of molecules, and a decrease in the probability that they will react upon colliding (Eckert et al. 1990), which should retard hydrolysis of different substrates and reduce the efficiency of their digestion.

The similarity of the absorption efficiencies of *Argopecten nucleus* and *Nodipecten nodosus* agree with results obtained in comparisons of absorption efficiencies among bivalve species, including *Mulinia edulis* and *Mytilus chilensis* (Velasco & Navarro 2003, 2005) and *Mya arenaria* and *Placopecten magellanicus* (MacDonald et al. 1998). This indirectly suggests a similarity in the composition and/or activity of the digestive enzymes of the two species, possibly induced by being exposed to similar environmental conditions. It was demonstrated in *M. edulis* and *M. chilensis* that although the composition and activity of the digestive enzymes in their digestive glands and crystalline styles were different (Labarta et al. 2002), they had comparable absorption efficiencies (Navarro et al. 2003, Velasco & Navarro 2003).

Oxygen Consumption

Oxygen consumption by *Argopecten nucleus* and *Nodipecten nodosus* increased with the increase in microalgae concentration, and at the highest concentration tested, this rate decreased, demonstrating a similar response to that of the feeding rate. This showed that the costs of feeding activities, digestion and absorption were variable and depended on the food concentration. Similar results have been described for other bivalves such as *Donax vittatus* (Ansell 1973), *Aulacomya ater* (Griffiths & King 1979), *Mytilus edulis* (Thompson & Bayne 1972, Bayne et al. 1984, 1989), *Mya arenaria* (MacDonald et al. 1998), *Musculista senhousia* (Inoue & Yamamuro 2000), *Mulinia edulis*, *Mytilus chilensis* (Velasco & Navarro 2003), *Cerastoderma edule* (Navarro et al. 1992, 1994) and *Hiattella arctica* (Sejr et al. 2004). It is in contrast, however, with the finding that there was no influence of food concentration on oxygen consumption in *M. arenaria* and *Placopecten magellanicus* (MacDonald et al. 1998).

The increase in oxygen consumption by *Argopecten nucleus* and *Nodipecten nodosus* with increase in water temperature is explained by the positive effect of increase in temperature on the speeds of metabolic reactions (Eckert et al. 1990) and is in agreement with results from other bivalves such as *Ostrea edulis* (Beiras et al. 1995) *Crassostrea gigas* (Bougrier et al. 1995) and *Argopecten ventricosus* (Sicard et al. 1999). This behavior differs from that found for *O. edulis* (Beiras et al. 1995) and *Argopecten purpuratus* (Navarro et al. 2000) after being experimentally held at a different temperature for a relatively long period (3 wk); under these conditions the oxygen consumption did not vary with temperature, showing an acclimation of the organisms to manipulation of this parameter. According to Eckert et al. (1990), acclimation of tissues and organisms to different temperatures could occur because of the modification of sensitivity of enzymatic activity, changes in molecular structure of one or more enzymes, or to changes in the quantities of enzymes.

In spite of the similarities among feeding rates of the scallops, *Nodipecten nodosus* had greater oxygen consumption than *Argopecten nucleus*, suggesting that the latter species was more efficient than the former in utilization of this resource in carrying on its metabolic functions. In studies comparing oxygen consumption among bivalve species (MacDonald et al. 1998, Velasco & Navarro 2003), it was noted that the existence of interspecific differences in oxygen consumption coincided with parallel differences in feeding rates.

Excretion Rate

The decrease in excretion rate in *Argopecten nucleus* and *Nodipecten nodosus* with increases in food concentration contrasts with most comparable studies, as the more typical response has been a positive relation between these variables (*Mulinia edulis*, *Mytilus chilensis*, Velasco & Navarro 2003, *Hiatella arcaica*, Sejr et al. 2004), or even no relation at all (*Mya arenaria* and *Placopecten magellanicus*, MacDonald et al. 1998). It is known that bivalves use proteins stored in body tissues as energy sources when the food supply is incapable of satisfying metabolic requirements, resulting in an increase in the excretion rate (Bayne & Newell 1983). Therefore the lower ranges of food concentration tested in this study (10 and 20 cells μL^{-1}) may have been insufficient to supply the energetic demands of the two scallop species, which then had to rely on the catabolism of endogenous proteins.

The reduced excretion rates of *Argopecten nucleus* and *Nodipecten nodosus* at low water temperatures, particularly when the food concentration was 20 cells μL^{-1} or less, could be explained by a decrease in metabolism under these conditions, which could in turn, lower the metabolic demands of the organisms to a point at which they were not required to resort to the use of stored proteins. The same tendency has been observed in other bivalves such as *Ostrea edulis* (Beiras et al. 1995).

The excretion rate of *Argopecten nucleus* was similar to that of *Nodipecten nodosus*, similar to findings in interspecific comparisons under the same conditions in *Mya arenaria* and *Placopecten magellanicus* (MacDonald et al. 1998) and *Mulinia edulis* and *Mytilus chilensis* (Velasco & Navarro 2003). The similarity in excretion rates of the bivalves, together with the similarities between absorption rates, suggested that the utilization of proteins in the two species comparisons were quite similar.

Scope for Growth

The positive high correlation between scope for growth and feeding rates, and the low values of oxygen consumption and excretion indicated that the energy acquisition by feeding was more important than the energy output in determining the values of scope for growth. Because values for ingestion and absorption depend on the filtration rate, it can be assumed that the filtration rate is the main determinant of physiological condition in *Argopecten nucleus* and *Nodipecten nodosus* under the conditions tested in the present study. Similar conclusions have been derived for *Argopecten purpuratus* (Navarro et al. 2000), *Mya arenaria* and *Placopecten magellanicus* (Bacon et al. 1998, MacDonald et al. 1998), and *Mulinia edulis* and *Mytilus chilensis* (Velasco & Navarro 2002; 2003). Nevertheless, in species such as *Ostrea edulis* (Ansell & Sivadas 1973) and *M. edulis* (Velasco & Navarro 2002), under certain conditions the oxygen consumption may constitute an important portion of the energy absorbed, and may have an important effect on the growth potential.

The high growth potentials of *Argopecten nucleus* and *Nodipecten nodosus* when fed intermediate microalgal concentrations (40 cel μL^{-1}), as well as the low values obtained at the extremes of the algal concentration (10 and 60 cel μL^{-1}), are in accord with results obtained for *Aulacomya ater* (Griffiths & King 1979), and *Mytilus chilensis* (Velasco & Navarro, 2003). They differ, however, with findings from other studies, where scope for growth and algae concentration showed an inverse relation, as in *M. chilensis* (Navarro & Winter 1982), or a direct relation as in *Cerastoderma edule*, *Tapes decussatus* (Navarro & Iglesias, 1995), *Mulinia edu-*

lis (Velasco & Navarro 2003), *Mya arenaria* and *Placopecten magellanicus* (MacDonald et al. 1998). These differences in the responses of the scope for growth to food concentration may be caused by the utilization of more narrow ranges of food concentration in the laboratory than those to which the test organisms are accustomed in their natural habitats.

The scope for growth of *A. nucleus* was not influenced by temperature, showing that this species had great plasticity of physiological rates in relation to this factor. On the other hand, the scope for growth of *N. nodosus* was greater at the intermediate temperature in our study (25°C), where there was a high degree of sensitivity of the feeding rates in relation to temperature. The lowering of scope for growth at lower temperature was probably related to decrease in metabolic rate, and at high temperatures to the denaturation of related enzymes (Eckert et al. 1990). The direct relation between scope for growth and temperature coincide with that observed in other species such as *Cerastoderma edule*, *Tapes decussatus* (Navarro & Iglesias 1995), *Argopecten purpuratus* (Navarro et al. 2000) and *Pecten maximus* (Laing 2000). At extremes of food concentration, the scope for growth of *Nodipecten nodosus* was low, and independent of temperature, therefore under these conditions the negative effects of either the absence, or excess of food on the physiological condition of the organism nullified the positive effect of providing an optimal temperature of 25°C. Navarro and Iglesias (1995) found that at very low concentrations of food that the scope for growth of *Cerastoderma edule* and *Tapes decussatus* became negative and decreased with increase in temperature. In this study, the food concentrations were not so extreme as to produce negative scope for growth at which we might have observed a similar phenomenon.

It has been found that the optimal food concentration increases with the water temperature for *Arctica islandica*, *Modiolus modiolus* (Winter 1970) and *Pecten maximus* (Laing 2000). This relation was not observed in this study with either scallop species. In *Argopecten nucleus* the optimal food concentration was independent of temperature, because the optimal food concentration was found to be the same (40 cel μL^{-1}) at all the temperatures tested. Conversely, in *Nodipecten nodosus* the optimal food concentration increased with decrease in temperature. This response was probably because saturation of the alimentary system did not occur under low temperature conditions and high food concentrations, thus permitting continuance of high ingestion and absorption rates.

Similarities between the scope for growth in *Argopecten nucleus* and *Nodipecten nodosus* indicate that the two species may compete with equal efficiency under the same conditions of food concentration and temperature, based on the environmental conditions occurring in each of their natural habitats. Studies that have compared scope for growth between species with differing habitats (epifaunal and infaunal) have found interspecific similarities under certain shared feeding conditions, which may not occur under other conditions in which interspecific differences become manifest (MacDonald et al. 1998, Velasco & Navarro 2002, Savina & Pouvreau 2004).

In conclusion, this study found that: (1) the scope for growth and the feeding rates of *Argopecten nucleus* and *Nodipecten nodosus* increased with increased food concentration but decreased at higher and lower extremes of food concentration; (2) the scope for growth and feeding rates of *A. nucleus* were not affected by temperature, with the reverse true for *N. nodosus*, increasing at 25°C and decreasing at higher temperature (28°C); (3) *A. nucleus* and *N. nodosus* showed similar responses and values in all their physi-

ological rates, except for oxygen consumption, where *A. nucleus* displayed lower rates.

¹Huaihai Institute of Technology, Jiangsu Key Laboratory of Marine Biotechnology, Lianyungang 222005, P.R. China; ²Institute of Marine Fisheries, Jiangsu Province, Nantong 226007, P. R. China

ABSTRACT The first and second internal transcribed spacer (ITS1 and ITS2) regions of the ribosomal DNA from six species, *Meretrix meretrix*, *Cyclina sinensis*, *Mercenaria mercenaria*, *Protothaca jedoensis*, *Dosinia corrugata* and *Ruditapes philippinarum*, in the family Veneridae were PCR amplified and sequenced. The size of the ITS1 sequence ranged from 522–900 bp, which was the largest range so far reported for a bivalve species, with GC contents from 57.66% to 65.62%. The size of the ITS2 sequence ranged from 281–412 bp, with GC contents from 65.21% to 67.87%. Extensive sequence variation and obvious length polymorphisms were noted for both regions in these species, and ITS2 sequence similarity was higher than that of ITS1 across species. The complete sequences of 5.8S ribosomal RNA gene were obtained by assembling ITS1 and ITS2 sequences, and the sequence length in all species was 157 bp. The phylogenetic tree of Veneridae clams was reconstructed by using ITS2 containing partial sequences of both 5.8S and 28S rDNA, and corresponding sequence information in *Arctica islandica* (Dahlgren et al. 2000) as an outgroup species. Tree topologies indicated that *P. jedoensis* has a closer relationship with *M. mercenaria* than with other species.

KEY WORDS: Veneridae, rDNA, internal transcribed spacer, 5.8S rRNA gene, phylogenetic analysis, species identification

INTRODUCTION

The internal transcribed spacers (ITSs) of nuclear ribosomal DNA (rDNA) is one of the most extensively sequenced molecular markers, and the region is a component of a rDNA cistron, which consists of 18S, ITS1, 5.8S, ITS2 and 28S. ITSs exist in several hundred copies in most eukaryotes. They are located in one or several loci and distributed in one or several chromosomes. The nuclear rDNA copies within a genome can be highly homogeneous because of concerted evolution of intra and interchromosomal loci. ITS1 and ITS2 are noncoding regions located in rDNA between 18S and 5.8S rRNA genes, and between 5.8S and 28S rRNA genes, respectively (Insua et al. 2003, Jansen et al. 2006, Won & Renner 2005).

Because ITSs sequences show more divergence than their flanking coding regions and are easily amplified, they are routinely used to distinguish related species and to infer phylogenetic relationships from populations to families and even higher taxonomic levels (Coleman & Vacquier 2002). In bivalve mollusks, a variety of methods, such as PCR amplification alone, PCR amplification followed by restriction analysis or sequencing was used to differentiate related species (Ding et al. 2004, Fernández et al. 2001, Insua et al. 2003, Kenchington et al. 2002, López-piñón et al. 2002, Yu et al. 2000) and exploring the phylogenetic relationship (He et al. 2005, King et al. 1999, Vidigal et al. 2000, Vidigal et al. 2004, Yu et al. 2001) among bivalve species.

The family Veneridae is a group of bivalve mollusks prevalent in seawater all over the world. There are more than 500 species, many of which are commercially valuable and ecologically crucial because of their dominance in benthic communities. A study of the phylogenesis of Veneridae was carried out using partial sequence of the mitochondrial 16S rRNA gene (Canapa et al. 2003).

The purpose of this study is to amplify and sequence the ITS1 and ITS2 regions of 6 Veneridae species, *Meretrix meretrix*, *Cyclina sinensis*, *Mercenaria mercenaria*, *Protothaca jedoensis*,

Dosinia corrugata and *Ruditapes philippinarum*, to provide the basic characteristics of these sequences and to assess the similarity among species. The results from this study will provide useful information in species identification and phylogenetic analysis of Veneridae clams.

MATERIALS AND METHODS

Sample Collection and DNA Extraction

Specimens of *Meretrix meretrix* and *Cyclina sinensis* were collected from Dalian, Liaoning province, China, and *Mercenaria mercenaria*, *Protothaca jedoensis*, *Dosinia corrugata* and *Ruditapes philippinarum* belonging to five subfamilies of Veneridae, from Lianyungang, Jiangsu province. Total genomic DNA was extracted from approximately 50 mg of adductor muscle following a modified CTAB protocol (Winnepenninckx et al. 1993). Briefly, the tissue was incubated for 15 min at 55°C in 600 µl CTAB buffer containing 25 µl 10 mg/mL proteinase K, homogenized with a pestle, and incubated for an additional 60 min. After extractions with saturated phenol and then chloroform: isoamyl alcohol (24:1), genomic DNA was ethanol-precipitated, resuspended in 50-µl TE (10 mM Tris-HCl, pH 8.0, 1 mM EDTA) and stored at –20°C for future use.

PCR Amplification and Sequencing

ITS1 region was amplified using ITS1-F (5'-GGTGAACCT-GCGGATGGA-3') and ITS1-R (5'-GCTGGCTGCGCTCT-TCAT-3') as primers, which anneal to the 3' end of 18S ribosomal RNA gene and the 5.8S ribosomal RNA gene, respectively. ITS2

Figure 1. Approximate locations of primers used for ITS1 and ITS2 amplification. Numbers below boxes refer to numbers of base pairs, ITS1 = first internal transcribed spacer, ITS2 = second internal transcribed spacer, ETS = external transcribed spacer

*Corresponding author. E-mail: CHL3139@163.com

Figure 2. Continued

The forward and reverse sequences were assembled using SeqManII software in DNASTar Package version 5.01 to obtain ITS1 and ITS2 sequences, and each of the different sequences was registered as an ITS1 or ITS2 haplotype in GenBank. Each newly determined sequence was checked against existing haplotypes using DNASTar and then the sequence was registered as a new haplotype. Because ITS1-R and ITS2-F primers anneal to the same region in

5.8S rDNA (Fig. 1), ITS1 and ITS2 can be assembled into an ITS, and the complete sequence of 5.8S ribosomal RNA gene can be obtained. The boundaries of the coding and spacer regions were determined by comparison with the sequence information of *Arctica islandica* (GenBank accession No. AF 202106). The sequences were edited and analyzed using the program EditSeq. ITS sequences containing the 5.8S ribosomal RNA gene across six species were aligned using program MegAlign of DNASTar package using the Clustal W method. The trees were produced by Neighbor-Joining (NJ) and Maximum parsimony (MP) methods using MEGA software Version 3.1 (Kumar et al. 2004).

RESULTS

The ITS1 and ITS2 regions were PCR amplified and sequenced among six species, the ITS1 and ITS2 were assembled into a single ITS sequence. For *M. meretrix*, *M. mercenaria*, *D. corrugata* and *R. philippinarum*, the identical ITS sequences were detected between 2 individuals within a species and named haplotypes WD1, YL1, BL1, FL1, respectively. For other species, *C. sinensis* and *P. jedoensis*, the ITS sequence were different between 2 individuals within a species and were named haplotypes QD1, QD2 for *C. sinensis*, and JL1, JL2 for *P. jedoensis*. Figure 2 showed the alignment of the ITS sequences including 5.8S rDNA, spanning 18S and 28S rDNA among eight haplotypes from six Veneridae species, and Table 1 displayed the length and GC contents of ITS1, 5.8S ribosomal DNA, and ITS2, and GenBank accession number.

Sequence Analysis of the First Internal Transcribed Spacer

The length of ITS1 sequence ranged from 522 bp to 900 bp, and GC contents from 57.66% to 65.62% in six species (Table 1). As seen in Table 1 interspecific ITS1 sequences showed remarkable divergence and obvious length polymorphism. The GC contents in ITS1 were higher than AT contents in all species. *M. meretrix* had the longest ITS1 sequence (900 bp) with 61.67% GC contents, and two trinucleotide microsatellites (AGT)_n were observed (Fig. 2). As well, a repeat sequence (AGT)_n GAAAAA(G)GCGAAG-GAGCCGCTGGCCCTTC was found occurring twice in ITS1 region in this species. *D. corrugata* had the shortest ITS1 sequence (522 bp) with 57.66% GC contents. *P. jedoensis*, *M. mercenaria*, *R. philippinarum* and *C. sinensis* had intermediate ITS1 size, 864 bp, 679 bp, 632 bp and 585 bp, respectively. A dinucleotide microsatellite (TA)_n was observed in the ITS1 region of *C. sinensis* (Fig. 2).

ITS1 sequences of six species were aligned. The percentages of sequence divergence and identity were showed in Table 2. Inter-

specific ITS1 sequence divergences were very high, because of the presence of transition, transversion and indels (insertions/deletions). The percentages of interspecific sequence divergence were from 27.2% (*M. mercenaria* and *P. jedoensis*) to 102.6% (*M. meretrix* and *R. philippinarum*). *P. jedoensis* exhibited 0.1% intraspecific sequence divergence between two individuals. For other species, *M. meretrix*, *C. sinensis*, *M. mercenaria*, *D. corrugata* and *R. philippinarum*, the ITS1 sequence was identical between two individuals within a species.

We found one relatively conserved motif in the ITS1 region across the six species of Veneridae (Fig. 2), with a size of 54 bp showed 18 polymorphic sites, 12 of which were transition and six were transversion.

Sequence Analysis of the Second Internal Transcribed Spacer

The length of ITS2 sequences ranged from 281 bp to 412 bp and GC contents from 65.21% to 67.87% (Table 1). The interindividual variation for ITS2 was detected in both *P. jedoensis* and *C. sinensis*. In contrast, *M. meretrix*, *M. mercenaria*, *D. corrugata* and *R. philippinarum* had the same ITS2 sequences in two individuals. The GC contents of ITS2 sequences were higher than AT contents in all species. *M. meretrix* had the longest ITS2 sequence (412 bp) with 65.29% GC content. *P. jedoensis* had the shortest ITS2 sequence (281 bp to 282 bp) with 67.38% to 67.62% GC contents; *C. sinensis*, *M. mercenaria*, *D. corrugata* and *R. philippinarum* had intermediate ITS2 sequence (Table 1). A quadrunucleotide microsatellite (AGCG)_n in *M. meretrix* and three dinucleotied microsatellites (AG)_n in *M. meretrix*, *R. philippinarum* and *D. corrugata* were observed (Fig. 2)

ITS2 regions from 8 haplotypes in six species were aligned. Percentages of sequence divergence and identity were listed in Table 3. ITS2 showed remarkable interspecific sequence divergences and obvious length polymorphism but to less compared with ITS1. Percentages of interspecific sequence divergence were from 21.6% (*P. jedoensis* and *M. mercenaria*) to 80.7% (*M. meretrix* and *C. sinensis*). Intraspecific sequence divergences in ITS2 region between two individuals were detected in *C. sinensis* (0.5%) and *P. jedoensis* (1.1%). For other species, *M. meretrix*, *M. mercenaria*, *D. corrugata* and *R. philippinarum*, the ITS2 sequence was identical between two individuals within a species.

We also detected two relatively conserved motifs in ITS2 region across six species (Fig. 2). The first relatively conserved motif with a size of 31 bp displayed five transition or transversion polymorphic sites, and the second with a size of 24 bp showed three transition or transversion polymorphic sites.

Sequence Analysis of the 5.8S Ribosomal RNA Gene

Through assembling ITS1 and ITS2 sequences, we obtained complete sequences of the 5.8S ribosomal RNA gene of six Veneridae species. The length of the 5.8S ribosomal RNA gene was 157 bp in all species (Fig. 2), and the GC contents ranged from 57.96% to 58.60% depending on species. The sequence divergences ranged from 0.0% to 6.0% across six species (Table 4). The 5.8S rRNA genes contained 10 polymorphic sites in these species, four of which were transition and six were transversion. Moreover, *P. jedoensis*, *M. mercenaria*, *D. corrugata* and *R. philippinarum* showed identical 5.8S rDNA sequence.

Phylogenetic Analysis in Terms of ITS2 Containing Partial 5.8S and 28S Ribosomal RNA Gene Sequences

Using ITS2 spanning 5.8S and 28S rDNA sequences as a molecular marker, the phylogenetic tree of Veneridae clam was constructed using *Arctica islandica* (GenBank accession number AF202106) as an outgroup species with Neighbor-Joining (NJ) and Maximum parsimony (MP) methods (Fig. 3).

The topology of the tree by MP method was similar to that by NJ method. Tree topologies showed that six Veneridae species were in the same group and forming a clade. In Veneridae, *P. jedoensis* was first grouped with *M. mercenaria* with a high bootstrap value of 94% in MP tree and 99% in NJ tree and then formed a clade with *D. corrugata* with a lower bootstrap value of 66% in MP tree and 80% in NJ tree; in contrast, *M. meretrix*, *C. sinensis* and *R. philippinarum* formed a monophyletic group. This indicated that *P. jedoensis* and *M. mercenaria* has a closer relationship than other species.

In contrast to ITS2, the construction of phylogeny using ITS1 was not applicable because of some disadvantages, such as ITS1 length variation, the presence of tandem repeated sequences, and

large number of indels. ITS1 sequences analysis, using MP and NJ methods, gave poor resolution in genus level. Therefore ITS1 was not used for phylogenetic analysis.

DISCUSSION

The current study provided information about the nucleotide sequences of ITS1 and ITS2 regions, complete sequence of the 5.8S ribosomal RNA gene in six Veneridae clams (*M. meretrix*, *C. sinensis*, *M. mercenaria*, *P. jedoensis*, *D. corrugata* and *R. philippinarum*). Their characteristics and variation were demonstrated through PCR amplification and sequencing. The length of ITS1 in the family Veneridae were longer than that in four Pectinidae scallop with size 209 bp to 276 bp for ITS1 and 270 bp to 294 bp for ITS2 (Insua et al. 2003), respectively. It should be noted that the length range in ITS1 reported in the current study was among the largest observed in bivalves. The size of ITS is species-dependent and the difference could be significant among species. The largest ITS1, such as that in Ladybird beetle *Exocomus quadripustulatus*, was as long as 2572 bp (Von der Schulenburg et al. 2001), and the shortest one only 70 bp to 80 bp in *Acropora* species (Odorico & Miller 1997). Depending on species, the length of ITS2 can be twice or more that of ITS1 (Dahlgren et al. 2000, Fernández et al. 2001, Yu et al. 2000), both situation, the length of ITS1 similar to ITS2 or larger than ITS2 were also reported (Chen et al. 2002, Coleman & Vacquier 2002). The GC contents ranged from 57.66% to 65.62% for ITS1 and from 65.21% to 67.87% for ITS2 in Veneridae tested in the current study. These species had higher GC contents than other bivalve species. For instance, the GC contents in Pectinidae scallop were 43% to 49% for ITS1 or 44% to 49% for ITS2 (Insua et al. 2003) and 51.9% to 55.5% for ITS2 in Pearl Oyster (He et al. 2005). A frequent characteristic of spacers is a balanced GC content between ITS1 and ITS2, and this

also occurs in the Veneridae spacers, this fact could indicate the coevolution between the two spacers at the level of base composition.

Both ITS1 and ITS2 regions in family Veneridae exhibit extensive sequence variation and obvious length polymorphisms, as is similar to Crustacea *Eriocheir formosa* (Chu et al. 2001) and other bivalves (Ding et al. 2004). In this study, the construction of topology in Veneridae clam using ITS1 sequence information is not applicable because of the high length variation, the presence of tandem repeated sequences and large number of indels in ITS1. However, it may be useful in phylogenetic analysis at lower taxonomic levels, such as subspecies, breeds or population levels. In contrast, the interspecific ITS2 sequence similarity in these species were higher than that of ITS1, and considering the length of ITS2 were shorter than that of ITS1, providing advantage and convenience in designing primers and sequencing. ITS2 is an ideal candidate for the study of genetic structure in Veneridae. The further study on the efficiency for combining the method in the current study with other techniques, such as PCR-RFLP, is promising.

In this study, a relatively conserved motif in ITS1 region and two relatively conserved motifs in ITS2 region were found in these species. This indicated that these motifs might be involved in certain nucleotide acid-related functions, such as in rRNA processing (Insua et al. 2003). Beside, two trinucleotide microsatellites (AGT)_n in *M. meretrix* and a dinucleotide microsatellite (TA)_n in *C. sinensis* were found locating in ITS1 region, and a quadrinucleotide microsatellite (AGCG)_n and three dinucleotide microsatellites (AG)_n was found locating ITS2 region. These microsatellites may be served as good markers in future studies. In the bivalve species, a dinucleotide microsatellite (GT)_n and a trinucleotide microsatellite (TAC)_n were found in ITS sequence of *Lasmigona* (King et al. 1999), but so far there has been no report from Veneridae.

Although interindividual sequence divergences in ITS1 and ITS2 regions were detected in *C. sinensis* (0.3% for ITS2) and *P. jedoensis* (0.1% for ITS1 and 0.6% for ITS2). Because of the presence of polymerase and sequencing error, the sequences cannot be thought as different only if when sequence divergence more than 0.9% (Kong et al. 2002). *C. sinensis* and *P. jedoensis* showed no intraspecific variations in ITS1 and ITS2. The 5.8S ribosomal RNA genes were highly conserved across these species studied in the current study, and had a length of 157 bp, which was reported in other bivalves, such as Pectinidae scallop species (*A. opercularis*, *M. varia*, *H. distortus*, *P. maximus*) (Insua et al. 2003) and *Arctica islandica* (Dahlgren et al. 2000).

The spacer regions, ITS1 and ITS2, of the rDNA are widely and routinely used in analysis of species relationships by using a phylogenetic reconstruction method in various organisms. It was successfully applied in analysis of phylogenetic relationship among the *Biomphalaria* species and among Pearl Oysters, and the conclusions from phylogenetic tree were well in agreement with those from analysis based on morphological systematics and other molecular techniques, such as polymerase chain reaction and restriction fragment length polymorphism analysis (He et al. 2005, Vidigal et al. 2000, Vidigal et al. 2004). Our study demonstrated that ITS1 provided weak phylogenetic signal in discrimination of Veneridae, whereas, ITS2 regions were effective in identifying phylogenetic relationships among Veneridae species. In this study, the tree obtained by ITS2 sequence analysis revealed that *P. jedoensis* and *M. mercenaria*, belonging to subfamilies Chioninae, has a close relationship than other species, belonging to subfamilies Meretricinae, Tapetinae and Cyclininae. Phylogenetic analysis of ITS2 sequences through both methods generated trees with similar topologies that were very concurrent with the morphological taxonomy proposed by Keen. Therefore ITS2 sequence characteristics are an efficient tool in reconstruction of evolutionary

Figure 3. Tree topology constructed in terms of ITS2 spanning 5.8S and 28S rDNA sequences across eight haplotypes from six species of Veneridae, *P. jedoensis* (JL1, JL2), *M. mercenaria* (YL1), *D. corrugata* (BL1), *M. meretrix* (WD1), *R. philippinarum* (FL1) and *C. sinensis* (QD1, QD2), with *Arctica islandica* as an outgroup species using (A) Maximum parsimony (MP) method and (B) Neighbor-Joining method. Numbers represents bootstrap percentages. The topologies were tested using bootstrap analyses (10,000 replicates).

relationship among these organisms, and they can be applied in establishment of species relationship, or reevaluation of the traditional taxonomy.

AMPELISCA AMPHIPOD TUBE MATS MAY ENHANCE ABUNDANCE OF NORTHERN QUAHOGS *MERCENARIA MERCENARIA* IN MUDDY SEDIMENTS

CLYDE L. MACKENZIE, JR., ROBERT PIKANOWSKI AND DONALD G. MCMILLAN

James J. Howard Marine Sciences Laboratory, Northeast Fisheries Science Center, National Marine Fisheries Service, NOAA, 74 Magruder Road, Highlands, New Jersey 07732

ABSTRACT Field surveys in southeastern Raritan Bay and laboratory studies from 1999 to 2005 were conducted to compare the characteristics of mud and sand habitats in relation to the abundance of the northern quahog (*Mercenaria mercenaria*). In 2000, the population density of quahogs was about 15 times higher in the mud habitat than in the sand habitat. In addition, the mud habitat also had a dense population of the amphipod *Ampelisca abdita* (about 24,000 m⁻²) associated with it. This species produces mats of tubes over the bottom. The sediment surface of the mud was comprised mostly of fecal pellets, the majority of which was produced by *A. abdita*. In contrast, the sand habitat did not have *A. abdita* tubes or much erect surface structure; its sediments were comprised of medium grain sand ($\phi = 1.17$ – 1.4). In southeastern Raritan Bay, the principal quahog predators are the longwrist hermit crab (*Pagurus longicarpus*), Atlantic oyster drill (*Urosalpinx cinerea*), and xanthid mud crabs. Collectively, they were >7 times more abundant in the sand habitat than in the mud habitat. We suggest that quahogs are abundant in the mud habitat because the presence of the tube mats probably reduces water siltation, encourages settlement of larval quahogs and deters predation on the quahogs.

KEY WORDS: *Mercenaria*, *Ampelisca*, habitat, pellets, sand, tube mats, predators

INTRODUCTION

Northern quahogs (*Mercenaria mercenaria*) can be found in estuaries along the Atlantic coast of North America from the Gulf of St. Lawrence to the Florida keys (Harte 2001). In 2004, the United States commercial landings of 9.4 million pounds (meats) of northern quahogs exceeded landings of any other estuarine bivalve; their ex-vessel value was \$37.8 million (Pritchard 2005). Fishermen typically harvest quahogs in sand or muddy-sand sediments, but quahogs are nearly always scarce in soft mud habitats (Rhoads & Young 1970, Rhoads 1974, Fegley 2001, Mann et al. 2005). This scarcity is apparently caused by high silt concentrations in the water close to the bottom (Rhoads & Young 1970, Murphy 1985). The silt clogs the digestive tract of larval quahogs and slows the growth of sedentary quahogs (Davis 1960, Bricelj et al. 1984). Most field studies of quahogs have emphasized the suppressing effects of predators on quahog abundance as summarized by MacKenzie (1977), Kraeuter (2001) and MacKenzie et al. (2002).

In southeastern Raritan Bay, New Jersey, in contrast to the other locations outside of Raritan Bay, quahogs are abundant in mud areas located in the bay's broad central area, and they are far more abundant there than in its sand areas that extend from its shores to the mud area (Celestino, 2003). A major difference between the mud and sand habitats in Raritan Bay is the presence of dense tube mats of the ampeliscid amphipod, *Ampelisca abdita*. *A. abdita* ranges from Maine to at least Florida, and produces dense masses of tubes (Stickney & Stringer 1957, Mills 1967, 1969) (Table 1). For this study, from 1999 to 2003, we examined several features of the mud and sand habitats in southeastern Raritan Bay that may explain the difference in quahog abundances between the two habitats. Particular emphasis was placed on describing the autecology of *A. abdita*, including its distribution, its persistence in the area through time, its number of generations per year and the temporal appearance of its tubes. In the Discussion, we compare our findings with those in the literature on the autecology of the quahog and suggest why the presence of *A. abdita*

may be the reason the quahog abundance is high in the mud area of southeastern Raritan Bay.

Characteristics of Southeastern Raritan Bay

The deeper areas of southeastern Raritan Bay primarily consist of mud sediments that extend over an area of about 30 km² (Fig. 1). The water depth averages about 7 m (range, 3.4–8 m) at low tide. The shallower areas that extend from the shorelines offshore to the mud areas consist primarily of sand sediments and have a total area of about 18 km². At their midpoints from the southern and eastern shores to the edges of the mud areas, water depths over the sand areas range from 3–4 m and 1–2.5 m, respectively, at low tide. Salinities in this part of the bay are about 26‰ during summer and 21‰ to 24‰ during winter (Cerrato et al. 1989). Surface water temperatures average 21°C to 24°C during summer, 0.4°C in early February, and 6°C to 7°C during March.

In the late 1980s and early 1990s, the mud area of southeastern Raritan Bay had relatively few northern quahogs and a large number of starfish (*Asterias forbesi*) (Cerrato et al. 1989, MacKenzie & Pikanowski 1999). By the mid 1990s and thereafter, the starfish were no longer present and the quahogs became abundant (MacKenzie & Pikanowski 1999). In 2000, the State of New Jersey Department of Environmental Protection surveyed the quahog abundance in southeastern Raritan Bay. Its population density was about 15 times higher in the mud than in the sand habitats: 14.9 quahogs m⁻² versus 1.0 quahogs m⁻² (Fig. 1) (Celestino 2003). Since the mid 1990s, southeastern Raritan Bay has had a year-round commercial fishery for quahogs. It consists of 20–100 boats, each with one fisherman using a bull rake. The fishermen harvest quahogs almost exclusively from the mud area.

In 1974, *A. abdita* was scarce in southeastern Raritan Bay (Steimle & Caracciolo-Ward, 1989), but it was abundant and widespread in 1986 in the mud area (Cerrato et al. 1989). It is not known when *A. abdita* became abundant between 1974 and 1986. It is assumed that it was abundant between 1986 and 1999, but there are no data to prove this. *A. abdita* occupy tubes about 3.5 cm long and 2.5–3.5 mm wide at the mouth end. The tubes are flattened laterally, and are composed of nonchitinous, pliable organic material. Each *A. abdita* forms a tube by secreting mucus around

E-mail: Clyde.Mackenzie@noaa.gov

TABLE 1.
Abundances of *Ampelisca abdita* in three northeastern United States estuaries.

Location	Number m ⁻²	Reference
Long Island Sound	7,000 to 80,450	Sanders et al. (1962)
Jamaica Bay, NY	18,000 to 80,000	Franz and Tanacredi (1992)
Raritan Bay	989 to 57,185	This study

its body. This mucus collects surface sediments on the tube's outer surface as the amphipod forms it. The Raritan Bay tubes are covered with a continuous layer of brown fecal pellets and finer particles held in place by the mucus. The tube lining is smooth and parchment-like, and lacks attached sediments. The top opening of the tube becomes its mouth and the bottom opening is gradually attenuated. About two-thirds of the tube length extends vertically into the water; the remainder is anchored in the sediment (Fig. 2).

Mills (1967, 1969) has made the only previous extensive observations of *A. abdita* in its natural habitat, studying them on an intertidal sandy flat in Barnstable, MA. He found that the abundance of *A. abdita* was irregular. The substrate sediments were stable when the mats were present, but unstable when absent. The abundances of associated macroinvertebrate species fluctuated accordingly.

A. abdita feeds at the tube mouth collecting diatoms, probably flagellates, amorphous organic material and clay-silt grains. It digests the living and organic matter, and forms the clay-silt grains and diatom cases into pellets to be cast onto the surface substrate below them (Mills 1967, Redmond et al. 1994).

Each generation of *A. abdita* is short-lived, the males and females producing one brood of juveniles. Adults mate in the water column (Mills 1967, Borowsky & Aitken-Ander 1991) and die shortly afterward. After about 2 wk in brood pouches of the females, the juveniles are about 1.5 mm long, and they are released

from their tubes. The females then die shortly afterward. The juveniles construct a new mass of tubes (Mills 1967).

The planktonic invertebrates in Raritan Bay include copepods (mainly, *Acartia tonsa* in summer and *A. clause* in winter), polychaete and nemertean larvae, amphipod zoeae, barnacle nauplii, mysid larvae of shrimp, cyprids, crab zoeae, gastropod veligers and fish larvae (Yamazi 1962, Jeffries 1964, Croker 1965). The plankters presumably produce large quantities of fecal pellets. Recent studies have shown that copepods break down most fecal pellets distributed through the water (Hofmann et al. 1981, Bathmann et al. 1987, Lampitt et al. 1990, Noji 1991, Noji et al. 1991, Viitasalo et al. 1999). As they descend onto the bottom, the fragmented pellets likely mix with settled phytoplankton and become a component of the sediment that accumulates with the *A. abdita* pellets in the mud habitat. At least eight fish species are present seasonally; some prey on *A. abdita* (Wilk & Silverman 1976, Collette & Klein-MacPhee 2002).

MATERIALS AND METHODS

Benthic Sampling

Fifty-four stations located in the mud habitat were sampled to determine the extent and the characteristics of the *A. abdita* tubes. At each station, two samples were taken with a Petite Ponar hand grab with an opening of 15 cm × 15 cm. The samples were brought aboard the vessel, the hand grab was opened, and then a shallow sample was scraped from the sediment surface into a beaker, and later viewed under a dissecting microscope, as proposed by Watling (1991). The pellets were measured and photographed using a scanning electron microscope at the EM Facilities, Nelson Biological Laboratories, Rutgers University, Piscataway, NJ. Sediment was collected from the sand areas to determine their grain sizes (ϕ value). This was done by passing them through a stack of sorting screens.

The total organic carbon (TOC) in the *A. abdita* tubes was determined by collecting them at several mud stations. The TOC in the sand sediments was determined by taking cores of bottom sediments on January 17, 2003. The tubes and sediments were spooned separately into small glass jars aboard the vessel. The samples later were placed in a refrigerator overnight, and the tubes

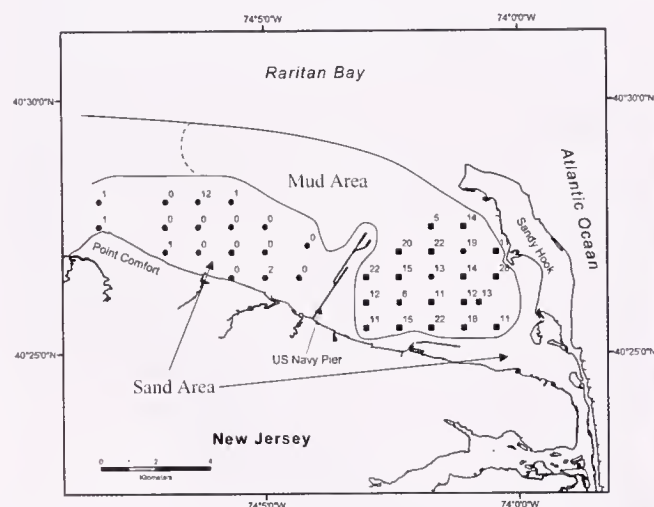

Figure 1. Abundance (number m⁻²) of >30 mm northern quahogs, *Mercenaria mercenaria*, in mud and sand areas in southeastern Raritan Bay (Celestino 2003). The mud area is outlined. The study's sampling area for examining the autecology and the abundance of *A. abdita* and quahog predators extended throughout the mud area to the broken line to the west. The abundance of quahog predators was surveyed in the two sand areas.

Figure 2. Section of bottom (side view) in southeastern Raritan Bay showing mass of *A. abdita* tubes. The oxidized layer directly beneath them consists of pellets. An anaerobic mud layer lies below it.

afterward were washed of loose particles under a freshwater faucet. The tubes and sand were put into separate aluminum cups and dried at 110°C for at least 24 h, weighed and then held in a muffle furnace at 510°C for 4 h and reweighed. The weight loss in the furnace was considered to be the percentage of TOC present.

The *A. abdita* tubes were sampled on 37 dates from August 22, 2001 through October 17, 2005. Most but not all stations were sampled on every survey date. Upon retrieval, the grab cover was opened and the extent of coverage of amphipod tubes, from 0% to 100%, was estimated visually. A surface with 0% coverage had no tubes, whereas a surface with 100% tubes was entirely covered with a dense mass of erect tubes (Fig. 3A). In addition, the age of the tubes at each station was recorded, as new (recently formed), middle-aged (upright but obviously not new or disintegrating), or old (disintegrating) (Fig. 3B). The contents of the grab were emptied into a 0.5-mm mesh sieve, spooned into labeled jars, and later in the day buffered formalin was added to the jars to preserve the sample. After 4 to 5 days, the formalin was replaced with 70% alcohol. The *A. abdita* and their tubes were counted using a dissecting microscope.

The relative abundance of predators was determined by sampling four fixed stations spaced across each of the mud and sand habitats with a specially designed dredge. The dredge had a mouth opening 60-cm wide. The blade at its bottom was 7-cm wide and angled at 45° so the predators in its path would slide up and into the fine-meshed bag (2-mm mesh openings) of the dredge. A planing board, 12.5-cm wide, was fastened 60 cm ahead of the mouth and positioned at the same level as the mouth to kick up predators from the bottom to collect in the bag. The dredge was towed along the bottom at a speed of 1.5 knots for 4 min at each station. When retrieved, its collected material was bagged and the predators later were identified and counted. The eight stations were sampled every 4–6 wk on 10 dates during 1999 (April 12 to October 22), on 8 dates in 2000 (January 26 to August 22), and on 2 dates in 2001 (May 9 and September 20).

Laboratory Observations

A. abdita were observed constructing its tubes in laboratory pans to aid in explaining its distribution in the mud and sand sediments. Three types of sediments were tested in plastic pans, 20 × 35 cm and 13-cm deep. Each pan received a different sediment: (1) medium-sized sand; (2) a collection of mud from the surface of the mud habitat and (3) an inorganic paste consisting of fullers earth (clay) and raw seawater. To prepare the mud, it was spray-washed with seawater through a 0.63 µm sieve to break up any *A. abdita* pellets. The three sediments were spread in a layer 5 mm thick over the pan bottoms. Trays were then filled with raw seawater and air stones added. Finally, about 500 *A. abdita* were scattered across the bottom of each pan.

RESULTS

The entire mud area was covered with dense mats of *A. abdita* tubes (Figs. 2, 3a, 3b); its sediment surface consisted of a layer of fecal pellets mixed with a relatively small mixture of silt, clay, fecal fragments, and other organic matter. The pellets were of 2 distinct sizes. The *A. abdita* pellets are 110–140 µm long (Fig. 4); the others are about 450 µm long. They are rod-shaped with rounded ends. As viewed under a dissecting microscope and a scanning electron microscope, they consisted of clay, silt and diatom shells probably held together by mucus. The *A. abdita* pellets were far more numerous than the larger pellets and they usually occupied about 90% of the space. The pellets were whole for a vertical distance of about 1 cm below the sediment surface. At distances between 1 and 2 cm below the surface, they were partially eroded (the larger pellets disintegrated more slowly than the *A. abdita* pellets), and below them the sediment consisted of anaerobic black silt. The TOC concentrations in *A. abdita* tubes were 10.8% and 13.2% in two determinations on January 17, 2003.

Ampelisca Abdita Tube-pellet mud habitat

The *A. abdita* tube mats were consistently present over the entire mud area. The tubes usually covered the mud surface so

Figure 3. *Ampelisca abdita* bottom habitat. A. Mass of freshly formed *A. abdita* tubes. B. Bottom surface of decaying tubes and visible sediments; this depicts a late stage in the generation of *A. abdita* just before a new generation will settle and form a fresh mass of tubes.

Figure 4. An *Ampelisca abdita* fecal pellet viewed under a scanning electron microscope.

completely that it was not visible. This was especially true after a new formation of tubes by the juvenile *A. abdita*. Year-round sampling, which included observations of their appearances (new, middle-aged or old), showed that *A. abdita* has three breeding cycles per year. New generations settled onto the bottom and constructed new tubes in May–June, September–October and December–January. The new tubes usually were spaced densely, and so the settling of *A. abdita* juveniles must compete strongly for available space. Several weeks after the new tubes were constructed, they slowly began to disintegrate and lay flat on the bottom. At this time, the sediment surface was visible between the tubes (Fig. 3B).

The next generation of juvenile *A. abdita* and their tubes did not settle and construct its tubes over the entire 30 km² all at once, but rather large sections, as much as a third of the area was settled at a time, and then another large section was settled. The time to settle the entire area was three or more weeks.

The tube coverage of the mud habitat averaged 62% (range, 36% to 96%)/sampling day from August 2001 through October 2005 (Fig. 5). Some of the lower values were recorded during the period when the tubes were decaying. While examining the collections in the grabs, no small quahogs of any size were observed among or on the surfaces of the masses of tubes. A small number of dwarf surfclams *Mulinia lateralis* sometimes were present on the tubes and in the sediment beside them.

The numerical abundance of *A. abdita* was determined on 6 dates in 2001, 2002 and 2003 by counting their numbers in single samples from 2–8 sampling stations (34 determinations). As projected to a square meter, its density averaged 23,700 m⁻² (range, 989–57,185 m⁻²) (Table 1).

On October 23, 2001, 7 stations with 100% coverage had from 29,000–98,000 tubes m⁻²; a grab sample with 75% coverage had 25,000 tubes m⁻² and a grab sample with 45% coverage had 14,000 tubes m⁻². On this date, the number of tubes present was about the same as the number of *A. abdita* present: an average of 23,290 tubes and 23,536 *A. abdita* m⁻² at the 7 stations.

Sand Habitat

The sediment in the sand habitats was medium sand ($\phi = 1.17$ –1.4). In the broad area off the south coast of the bay, the sand surface was essentially free of any emergent structures. In contrast, the narrower sand habitat that extends westward from Sandy Hook

had scattered quahog shells covered with bryozoans and sponges and chains (stacks) of the common Atlantic slipper-snail (*Crepidula fornicata*). On January 17, 2003, the TOC was 0.29% at two areas in the sand sediments.

Predator Abundances

Quahog predators had a much lower abundance in the mud habitat than in the sand habitat. The longwrist hermit crab (*Pagurus longicarpus*), Atlantic oyster drill (*Urosalpinx cinerea*) and xanthid mud crabs were the most numerous quahog predators collected in our dredge. For the 20 sampling dates over three years, 1999 to 2001, their combined numbers at the four mud stations were 27 *P. longicarpus*, 11 *U. cinerea* and 175 xanthid mud crabs. The four sand stations had a combined total of 415 *P. longicarpus*, 131 *U. cinerea* and 899 mud crabs; or 15 times the number of *P. longicarpus*, 12 times the number of *U. Cinerea* and 5 times the number of mud crabs in the mud stations.

All years and stations were combined to test the main hypothesis, H₀: predator density is the same in mud and sand stations. The untransformed and log-transformed sampling distributions of all three species failed normality. Mann-Whitney rank sum tests found the lower mud densities were significantly different from the higher median sand densities of all three species with $P < 0.001$. Mean values of predators were lower in the mud collection also, but were not tested (Table 2). The mud samples showed a lower predator density than the sand samples.

The sand habitat also had some predaceous northern moon snails (*Euspira heros*) (Greene 1978, Haskin 1951); their sand collars were found in the dredge collections in May and June each year. The dredge also collected some lady crabs (*Ovalipes ocellatus*), Atlantic rock crabs (*Cancer irroratus*) and blue crabs (*Callinectes sapidus*). The mud stations had a total of 7 of these larger crabs, whereas the sand stations had 25.

Laboratory Observations

In the three laboratory trays, the 500 introduced *A. abdita* dug immediately into each sediment. The *A. abdita* released in the tray with a layer of medium sand did not construct tubes.

In the tray with mud, more than 100 *A. abdita* had formed short tubes within an hour. After 56 h, the tubes were about 14-mm long, less than half the length of the tubes in the mud substrate in Raritan Bay. All were upright, and they were covered with the fine organic

Figure 5. The percentages of the mud area covered by *Ampelisca abdita* tube mats during 2001, 2002, 2003, 2004, and 2005. The tubes were observed at every station, but the proportion of bottom covered at a particular station ranged from 0–100%.

TABLE 2.

Summary of the relative densities of the quahog predators *Pagurus longicarpus*, *Urosalpinx cinerea*, Xanthid mud crabs, and *Crangon septemspinosa* on mud and sand substrates. All years and stations are combined. Neither the untransformed nor log-transformed distributions passed normality tests. Mann-Whitney rank sum tests showed that all three species had significantly larger medians on sand at the $P > 0.001$ level, but *Crangon* was not significantly different.

Predator	Substrate	N ¹	Median	Mean	Significance
<i>P. longicarpus</i>	Mud	75	0.0	0.4	<0.001
	Sand	61	4.0	11.7

N¹—number of samples taken.

particles and silt that comprised the sediment. The particles collected on sticky mucus on the outside of the tubes as they were being formed in the midst of the sediment. The tubes did not grow further.

The *A. abdita* released in the tray whose bottom was covered with a paste of fullers earth constructed a small number of tubes—about 20 could be clearly identified. By the second day, the tubes had the overall shape of a typical tube but were much shorter. Their walls were constructed of tiny balls of fullers earth held together by mucus. Numerous fecal pellets that consisted of fullers earth were present on the sediment surface beside the tubes.

DISCUSSION

During the 5-y field study, the entire mud area was consistently covered by dense mats of *A. abdita* tubes. In contrast, populations of *A. abdita* and their mats in the shallow sections of Boston Harbor (Gallagher & Keay 1998) and Barnstable Harbor, Massachusetts (Mills 1967), were washed away by waves produced by strong wind storms. In southeastern Raritan Bay, the *A. abdita* are able to persist during windstorms because of its deeper water (7 m avg. depth), and shorelines that protect the area from wave action. Laboratory observations suggest that *A. abdita* does not occur in habitats where sediments consist of medium and coarse sand, because they have difficulty constructing their tubes with it. *A. abdita* construct tubes readily in sediments consisting of their own pellets, silt, and also fine sand. The *A. abdita* likely are present in the mud habitat because of its grain size rather than its high organic content. The laboratory observations also suggest that juveniles begin constructing tubes as soon as they land on the bottom and the tubes are built rapidly.

The *A. abdita* tubes were free of attached macrofauna and visible plants throughout the mud habitat at all times, as Mills (1967) had observed for *A. abdita* tubes in Barnstable Harbor. The cover of the tubes' surface with their pellets and smaller particles apparently prevents macrofauna from attaching and growing. Their absence obviously favors the persistence of the *A. abdita*. South-eastern Raritan Bay has abundant macrofauna that attach to the hard surfaces of shells and stones in the sand areas and they could be present in the mud habitat if it were suitable. The species include bryozoans, blue mussels (*Mytilus edulis*), common Atlan-

tic slipper-snails, red beard sponge (*Microciona prolifera*) and the egg cases of *U. cinerea*, three lined mudsnail (*Ilyanassa trivitatta*) and eastern mudsnail (*I. obsoleta*). In other locations, some benthic invertebrates produce calcareous tubes on which other macro-invertebrates can settle and grow and eventually kill them (Russ 1980, Qian 1999, Zuhlke 2001).

It was observed that for a few weeks before each of the breeding periods, the *A. abdita* tubes gradually disintegrate, leaving a surface of pellets and fine particles available for settlement and tube building by the next generation of juvenile *A. abdita*. Can these be the periods, especially the May–June period and lesser so the September–October and least in the December–January periods, when most larvae of benthic invertebrates, including quahog pediveligers, can settle in the substrate?

It is likely that the reasons the quahogs thrive in the *A. abdita* tube-pellet mud habitat in Raritan Bay are because the water near the bottom probably has little silt, the presence of the tubes favors the settlement of their pediveligers and quahog predators are scarce and have difficulty finding small quahogs among the tubes.

Some studies suggest that mud bottoms that lack surface tubes are marginal habitats for quahogs because of the silty water associated with them (Davis 1960, Rhoads & Young 1970, Rhoads 1974). The *A. abdita* tube mats and pellets and the amphipods modify the mud surface in Raritan Bay substantially. The mats cover and stabilize it, thereby minimizing the transport of silty sediments into the water during strong currents and the movements of fish and crabs (Hunt 2005). Moreover, the mud surface consists mostly of pellets that produce little turbidity even when swirled into the water. In addition, the *A. abdita* clear the water by capturing silt and forming pellets while feeding.

The presence of *A. abdita* tubes and their pellets may provide some positive attributes for settling quahog pediveligers. The tubes serve as baffles to slow water currents, a feature that has been shown to produce higher settlements of quahog larvae (Carriker 1961, Peterson 1986, Wilson 1990). The tubes also provide a shaded zone at their bases, another feature that attracts settling quahog larvae (Carriker 1961). The settling pediveligers, that are about 225- μ m long, are more stimulated to affix their byssus to sediment grains when among small grain sizes than when among larger sizes (Carriker 2001). The *A. abdita* pellets are about half the length of quahog pediveligers whereas medium-sized sand grains are much larger than the pediveligers.

The tube mats probably are poor habitats for the predators of juvenile quahogs in Raritan Bay. All are scarce on muddy bottoms with tube mats. The long wrist hermit crab is abundant on sandy bottoms that have little structural relief and the Atlantic oyster drill, and xanthid mud crab are most abundant among oysters and shells. Where they are present among the *A. abdita* tube mats in Raritan Bay, they probably have difficulty finding the juvenile quahogs. Mills' (1967) observation that eastern mudsnails (*Ilyanassa obsoleta*) disappeared from areas that became covered with *A. abdita* tubes in Buzzards Bay is another example of gastropod numbers being low in substrates densely covered with its tubes. Similarly, earlier studies have shown that habitats containing dense upright structures, such as shells, eelgrass (*Zostera marina*) and polychaete tubes have higher abundances of quahogs and other invertebrates in their sediments (MacKenzie 1977, Beal 1983, Peterson 1986, Peterson & Beal 1989, Zuhlke 2001). The structures probably provide them cover from predators, though other factors may also play a role.

In Virginia, quahogs are equally abundant in all water depths

from 3–21 m; they appeared to be slightly scarcer at a depth of 2 m (Mann et al. 2005). This suggests that in Raritan Bay, the depth difference between the mud area, 7-m avg., and the wide sand area off the south coast, 3–4 m, and smaller sand area off the east coast, 1–2.5 m, has little influence on the difference in quahog abundance in them.

Our study has described several aspects of the quahog's habitat in mud and sand bottoms in Raritan Bay. Because we conducted a survey and not an experiment, we did not control treatment; that is mud versus sand was not randomized. Because of the contiguity of the mud and sand sites and to the hydrodynamic processes causing sediment dichotomy, there are unaccounted for differences between the sites, the effects of which may confound the findings. This situation prevails for other similar surveys and cannot be helped.

Many questions remain. Do peliveligers actually settle in higher abundances among *A. abdita* tubes? Do peliveligers attach similarly to fecal pellets and sand grains? How do infaunal invertebrates, such as nematodes and polychaetes, interact with fecal

pellets? After mature *A. abdita* females breed with males in the water, what is their behavior? How do the tubes affect predation rates on juvenile quahogs? How do finfishes prey on the *A. abdita*? Do they swallow whole tubes? What caused the starfish to abandon southeastern Raritan Bay? Can starfish inhabit bottoms covered with these tubes? How abundant were quahogs in Southeastern Raritan Bay during periods when the *A. abdita* were scarce? Will the quahogs become scarcer in Raritan Bay if the *A. abdita* become scarce again?

REPRODUCTIVE PATTERN OF THE SQUALID CALLISTA MEGAPITARIA SQUALIDA FROM NORTHWESTERN MEXICO

MARCIAL ARELLANO-MARTÍNEZ,¹* MARCOS F. QUIÑONES-ARREOLA,²
BERTHA PATRICIA CEBALLOS-VÁZQUEZ¹ AND MARCIAL VILLALEJO-FUERTE¹

ABSTRACT The annual reproductive cycle of the squalid callista *Megapitaria squalida* living in the Ojo de Liebre lagoon was analyzed from January to December 2001. The reproductive activity was analyzed qualitatively (through histological analysis), defining five gonad development stages (undifferentiated, developing, ripe, spawning and spent). A quantitative analysis was also conducted (through the gonadic index and oocyte diameter) to correlate the reproductive activity with water temperature and salinity. Male and female gonads developed and spawned in parallel through time. *M. squalida* displays a clearly seasonal reproductive cycle in the Ojo de Liebre lagoon, with a long reproductive activity period (January to August) that coincides with the rise in temperature, plus a well defined inactivity period (September to December) with 100% of undifferentiated or spent organisms and the onset of which coincides with the temperature decrease. *M. squalida*'s reproductive cycle does not seem to be influenced by salinity variations in the Ojo de Liebre lagoon. The spawning size of *M. squalida* was determined at 92 mm SL at an approximate age of 2.2 y. However, some individuals started spawning at 64 mm SL. Marked differences were found in some aspects of the reproductive pattern of *M. squalida* compared with studies conducted in other sites, and the likely causes are discussed here.

KEYWORDS: reproduction, bivalve, *Megapitaria squalida*, histology, Mexican Pacific.

INTRODUCTION

The squalid callista *Megapitaria squalida* (Sowerby, 1835) is one of the most abundant bivalves in northwestern Mexico. It is distributed from the Ojo de Liebre lagoon in Baja California Sur, (including the Gulf of California) to Macora in Perú (Keen 1971). *M. squalida* lives in muddy and sandy bottoms at depths ranging from one to 120 m, and can reach up to 120 mm in body length (Singh et al. 1991).

Studies on growth (Castro-Ortiz et al. 1992), ecological aspects (Baquero & Stuardo 1977, Anguas-Vélez & Castro-Ortiz 1990, Singh et al. 1991), mantle anatomy (García-Gasca & García-Domínguez 1995), and reproductive aspects (Baquero & Stuardo 1977, Singh et al. 1991, Villalejo-Fuerte et al. 1996a, Baquero & Aldana 2000, Villalejo-Fuerte et al. 2000) have been conducted in *M. squalida*.

Although *M. squalida* is usually considered as a species with a low commercial value, in northwestern Mexico the fishery of this clam has intensified recently, resulting in an increase in production from 31.4 tons in 1996 to about 972 tons in 2004 (SAGARPA 2006). The above derives from the fact that the species is being captured, more and more, as an alternative resource when the main commercial species are unavailable because of the enforced fishing restrictions. *M. squalida* is captured throughout the year from the main water bodies along the state of Baja California Sur, including the Gulf of California and the Mexican coasts of Pacific Ocean. The capture regimen of *M. squalida* is based on previous studies of some populations from the Gulf of California (Singh et al. 1991, Villalejo-Fuerte et al. 1996a, 2000); however, the reproductive cycle varies with the geographic location, according to the species' specific phenotypic response to the particular environmental conditions in each location (mainly water temperature and food availability) (Porter 1964, Hesselman et al. 1989, Cruz & Villalobos 1993, Rodríguez et al. 1993).

Hence, a basic understanding of the reproductive cycle of *M. squalida* is needed for an appropriate timing of the fishing effort and the development of a sustainable fishery. Thus, the objective of this study is to determine the reproductive cycle of *M. squalida* in the Ojo de Liebre lagoon, located in the Pacific coast, and compare it with studies conducted in other localities.

MATERIALS AND METHODS

The Ojo de Liebre lagoon (24°02'N, 110°24'W) is located within the Sebastián Vizcaíno bay, in the west coast of the Baja California peninsula, Mexico (Fig. 1). There, 30 *M. squalida* adult specimens were collected per month by a scuba diver at 3- to 6-m deep from January to December 2001. The bottom water temperature and salinity were recorded at the time of sampling by means of a U-10 HORIBA water-quality analyzer. In the laboratory, total and soft body weights and shell length (SL) were recorded for each clam. To determine the extent of gonad development, the visceral mass of each clam (gonad included) was dissected and fixed in 10% formalin. Later, a section of tissue from the dorsal area of each visceral mass was dehydrated in alcohol and embedded in paraplast X-tra. Sections (7 µm) were placed on slides and stained with haematoxylin and counterstained with eosin (Humason 1979).

Because *M. squalida* does not exhibit sex dimorphism, specimens were sexed through histological analysis. Sex ratios were analyzed by month, testing the null hypothesis of a 1:1 sex ratio, using a chi-square test ($\alpha = 0.05$) (Zar 1996).

Qualitative characteristics were used to sort specimens into one of five arbitrary gonad stages previously established for the same species: undifferentiated, developing, ripe, spawning and spent (Baquero & Stuardo 1977, Villalejo-Fuerte et al. 2000). The relative frequencies of gonad-development stages throughout the year were obtained. This enabled the description of the reproductive cycle.

To obtain quantitative information on the reproductive activity, the oocyte diameter and a monthly gonad index were determined. Oocyte diameter was measured from digitalized images of histo-

logical sections by means of the SCAN PRO software (Version 5.0, Systat Software, Inc., Point Richmond, CA, USA). Oocytes were individually traced by hand with the pointer, and the software automatically measured the major- and minor-axis lengths. Then, both dimensions were averaged and this was considered as the estimated diameter. In this way, a monthly mean oocyte diameter was calculated. At least 100 oocytes were measured from each slide. Only oocytes showing a nucleolus were sampled, assuming that this structure is located at the cell center (Laruelle et al. 1994). Individuals with few measurable oocytes and extensive phagocytosis (i.e., "spent" specimens) were excluded following the criteria of Grant and Tyler (1983). A one-way ANOVA, followed by a Tukey posthoc mean comparison test, was used to assess significant differences between months. The monthly gonad index was computed using a numerical grading system (Heffernan et al. 1989). Four categories were established according to the degree of gonad development, with 0 = undifferentiated and spent, 1 = developing, 2 = partially spawned and 3 = ripe. The monthly gonad index was determined by multiplying the number of specimens assigned to each category by the category score, summing all such values and dividing this amount by the total number of clams analyzed. The monthly values of oocyte diameter and gonad index obtained, enabled to carry out correlation analyses of reproductive activity with temperature and salinity, using a Spearman-rank correlation analysis (Zar 1996). The STATISTICA (version 6.0) software (StatSoft, Inc. 2001) was used for all statistical analyses. The significance level (α) was set at 0.05.

The size at spawning in the population is defined as the smallest length at which the 50% of the cumulative frequency of sampled females and males are spawning (Somerton 1980). To establish the size at spawning in the *M. squalida* population, the

relative cumulative frequency of ripe and spawning organisms was fitted to a logistic model. Additionally, to have a gross estimation of the age at spawning in the population, the Bertalanffy growth equation ($L_t = 92[1 - e^{-0.545(t - 0.07)}]$) obtained for *M. squalida* by Castro-Ortiz et al. (1992) was used. However, for this study the L_∞ value (92) was replaced by a L_∞ value (128) calculated with the FISAT software (Gayaniilo et al. 1995) using length frequencies of individuals collected in the Ojo de Liebre lagoon.

RESULTS

A total of 384 specimens were collected, including 128 females (33.3%), 156 males (40.6%), and 100 (26%) undifferentiated specimens. The monthly sex-ratio analysis shows that a significant difference ($P < 0.05$) from the expected 1:1 ratio occurred in August, September and October (Table 1). However, the sex ratio for the total sample (0.83F:1M) did not differ significantly ($P > 0.05$) from the expected 1:1 ratio. Clams ranged in SL from 64 mm to 121 mm (mean = 91.3 mm, standard deviation = 9.5 mm).

The reproductive cycle of *M. squalida* in Ojo de Liebre showed a clear seasonal pattern (Fig. 2). The relative frequencies of gonad development stages throughout the year were obtained pooling females and males together, because no differences in the temporality pattern between sexes were observed. The development stage occurred from January to March, with a peak frequency in January (92.8%). Ripe clams were observed from February to August with a variable frequency. The spawning stage was observed from February to August, reaching the peak frequency in April, June, July and August (78% to 94%). From September to December 100% clams were inactive (undifferentiated and spent stages).

Oocyte diameter showed significant differences (one-way ANOVA, $P < 0.01$) throughout the year (Fig. 3a). Small oocytes (30.6–33.4 μm) were observed from January to March. Oocyte diameter increased considerably from April to July and August, when significantly larger oocytes (44.2–45.2 μm ; $P < 0.01$) were present. The above was consistent with histological observations, which revealed that the highest reproductive activity took place from April to August. From September to December all clams were spent or undifferentiated, so that oocyte diameter values could not be obtained.

TABLE 1.

Female and male frequencies, Chi square (χ^2) values and sex ratios of *Megapitaria squalida* by month. Numbers in bold indicate a statistically significant differences from a 1:1 ratio ($P \leq 0.05$).

Month	Female	Male	Total	χ^2	Sex Ratio F:M
January	13	9	22	0.73	1.44:1
February	15	17	32	0.13	0.88:1

TOTAL	115	138	253	2.09	0.83:1

Figure 2. Monthly percent frequencies of the different gonad stages of *M. squalida* throughout the study period in Ojo de Liebre lagoon, B.C.S. México.

Gonad index displayed a seasonal tendency throughout the year (Fig. 3b). From these data, a clear resting period from September to December was also apparent, whereas gonad index values were higher from April to August, coinciding with the ripe and spawning stages.

Seawater temperature showed a clearly seasonal variation in the Ojo de Liebre lagoon (Fig. 3c). The cold months (January to April and December) had temperatures under 18°C. The lowest temperatures were registered in January and February (15.9°C). The warmer months (July to October) had temperatures above 22°C. Water temperature reached its peak value (23.4°C) in August. Salinity in the Ojo de Liebre lagoon displayed a slight fluctuation (Fig. 3d). The minimum salinity occurred in January (33.4‰), and the maximum in March and May (34.3‰). The mean oocyte diameter and gonad index were positively correlated with temperature ($R = 0.86$; $P = 0.006$ and $R = 0.76$; $P = 0.03$, respectively), but not with salinity ($R = 0.24$; $P = 0.57$ and $R = 0.54$; $P = 0.17$, respectively).

To establish the size at spawning in the *M. squalida* population studied, relative cumulative frequency data of ripe and spawning organisms were fitted to the logistic model ($r = 0.99$, Fig. 4). The size at spawning in the *M. squalida* population was 92 mm SL, which may correspond to an age of 2.2 y old (according to our gross estimation). However, individual organisms may start spawning at 64 mm SL (1.2 y old).

DISCUSSION

Slight differences in seasonal gametogenesis and spawning patterns between males and females have been reported in some bivalves (Goodwin 1976, Sloan & Robinson 1984, Baron & Ciocco 2001). In our study, male and female gonads developed and underwent spawning in parallel through time, as reported in other bivalves (Villalejo-Fuerte et al. 2002, Choi & Chang 2003). This synchronization seems to be related to changes in water temperature, as reported by Gribben et al. (2004) for *P. zelandica*, and it is characteristic of species living in temperate zones.

Many studies point out that temperature is the most important environmental factor in the regulation of reproduction in bivalves (gametogenesis and spawning) (Giese & Pearse 1974, Sastry 1979, Barber & Blake 1981, Cruz & Villalobos 1993, Rodríguez et al. 1993, Wada et al. 1995), which may trigger or synchronize the

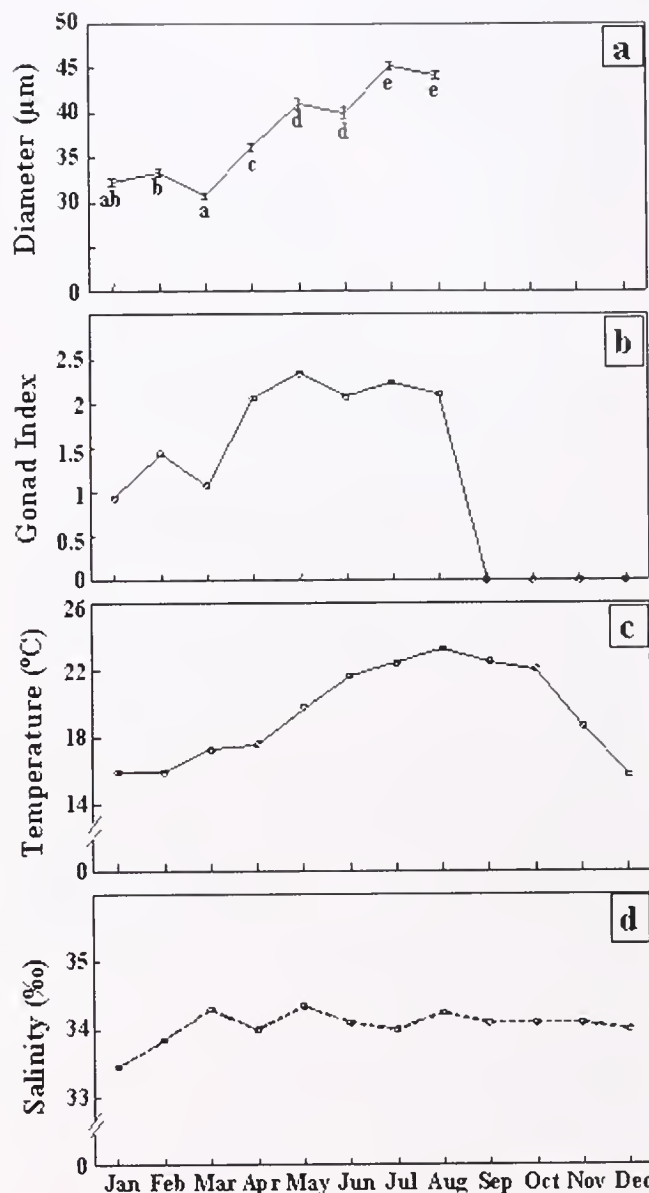

Figure 3. Temporal variation of the different variables analyzed throughout the year in the Ojo de Liebre lagoon. (a) Oocyte diameter, (b) gonad index, (c) bottom seawater temperature, (d) salinity. Oocyte diameter was analyzed by one-way ANOVA followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

“temporality” of the different development stages (Lubet 1983, Gallardo 1989). Thus, the rise in water temperature may stimulate gonad ripening (Giguere et al. 1994). In Ojo de Liebre, the reproductive activity of *M. squalida* (measured through the variation in the mean oocyte diameter and gonad index) was significantly and positively correlated with water temperature. The relationship between temperature and reproductive activity is well documented for other bivalves living in the Mexican Pacific coasts, including *Chione californiensis* (García-Domínguez et al. 1993), *Glycymeris gigantea* (Villalejo-Fuerte et al. 1995) and *Laevicardium elatum* (Villalejo-Fuerte et al. 1996b).

In Ojo de Liebre lagoon, *M. squalida* shows a clearly seasonal reproductive cycle. This includes an extended period of reproduc-

Figure 4. Length of spawning of *Megapitaria squalida* from Ojo de Liebre lagoon, B.C.S., México.

tive activity (January to August) coinciding with the period of temperature increase, followed by a well-defined reproductive inactivity (September to December) where 100% of organisms are either undifferentiated or spent, the onset of which coincided with the drop of temperature. Likewise, a seasonal reproductive pattern has already been reported in the same location for other bivalves such as *Nodipecten subnodosus* (Arellano-Martínez et al. 2004a).

However, although temperature undoubtedly affects reproduction, other environmental factors may seem to interact with it to determine the annual reproductive activity pattern in any given geographic area (Sastry 1970). In this sense, the variation in the onset of gonad proliferation in *Ruditapes decussatus* has been found to be caused by interannual salinity fluctuations (Shafee & Daoudi 1991), and spawning in *A. ventricosus* coincides with minimum and maximum salinity values (Luna-González et al. 2000). In other cases, extreme salinity values have been found to lead to a steady reduction in the duration of gonad development (Muranaka & Lannan 1984, Utting 1993). To this respect, salinity shows hypersaline gradients in the Ojo de Liebre lagoon (Lankford 1977), with salinities over 47 ‰ recorded in some areas (Contreras, 1985), being either shallow zones or as a result of human activities (brine discharges by the salt-producing company into some areas of the lagoon). However, in this investigation salinity in the study area (El Borbollón) was found to be relatively constant throughout the whole study period, likely caused by its closeness to the lagoon mouth. Thus, the reproductive cycle of *M. squalida* in this locality seems to be unaffected by salinity variations, be-

cause no significant correlation was found with this variable. This does not rule out the possibility that another clam bank located farther into the lagoon (where greater salinity variations occur) might be affected by this environmental factor. However, further research is required to obtain concluding results to this respect.

Currently, there is available information on reproductive aspects of *M. squalida* from four additional localities of the Mexican Pacific coast (Fig. 1): in the Gulf of California, from Bahía Concepción (Villalejo-Fuerte et al. 1996a), Bahía Juncalito (Villalejo-Fuerte et al. 2000) and Bahía de La Paz (Singh et al. 1991), and outside the Gulf of California, from Bahía Zihuatanejo (Baquero & Stuardo 1977), a site located in the southern Mexican Pacific coast. Our findings reported here differ substantially in some aspects with the studies mentioned earlier (Table 2). The most obvious difference refers to the temporality of the reproductive cycle, which might be associated with water temperature and/or food availability in each locality.

As mentioned earlier, in Ojo de Liebre lagoon *M. squalida* displays a marked interruption in the reproductive activity (high percentage of undifferentiated or spent organisms) from September to December. However, this complete interruption of the reproductive activity during the annual cycle was absent in any other locality, whereas the undifferentiated stage occurred only at low levels in some months (Singh et al. 1991, Villalejo-Fuerte et al. 1996a, Baquero & Stuardo 1977, Villalejo-Fuerte et al. 2000). This clear resting period at the Ojo de Liebre lagoon might derive from having included immature specimens. However, the range of sizes analyzed (64 mm to 121 mm SL) is larger than the size of the smallest specimen (42 mm SL) reported as having undergone spawning (Villalejo-Fuerte et al. 1996a), so that this finding is valid. In this sense, Baquero and Aldana (2000) point out that the undifferentiation or lack of reproductive activity periods is not species-specific requirements, but responses to environmental conditions. Villalejo-Fuerte et al. (2000) mention that the absence of a reproductive inactivity period in Bahía Juncalito may result from food being abundant throughout the year, so that the clam population produces gametes continuously. This situation might also occur in the other localities of the Gulf of California, as well as in Bahía Zihuatanejo. In contrast, the Ojo de Liebre lagoon has been regarded as an area with low food availability (Millán et al. 1987, Delgadillo-Hinojosa et al. 2002, Arellano-Martínez et al. 2004b) and low food quality (Arellano-Martínez et al. 2004b). This situation of low food availability and quality in Ojo de Liebre might lead to the marked resting period and foster a

TABLE 2.
Available information on reproductive aspects of *Megapitaria squalida*.

Locality	Sex Ratio F:M	Oocyte Diameter	Resting Period	Spawning Period (Main Period)	Source

marked energy storage/use cycle, as reported by Arellano-Martínez et al. (2004b) for *N. subnodosus* in the same locality. Nevertheless, further studies are required on this aspect to corroborate it for *M. squalida*.

On the other hand, in the case of the populations living in the Gulf of California and Bahía de Zihuatanejo, the ripe and spawning stages were present (although at different times and proportions) throughout the whole study period (Table 2), so that it is assumed that *M. squalida* from these localities displays a continuous reproductive cycle. This reproductive behavior has also been observed in other bivalves from tropical latitudes, including *Lacvivardium elatum* (Villalejo-Fuerte et al. 1996b), *Periglypta multicostata* (García-Domínguez et al. 1998), *Pinna rugosa* (Ceballos-Vázquez et al. 2000) and *Spondylus calcifer* (Villalejo-Fuerte et al. 2002). In contrast with the above, in the Ojo de Liebre population the ripe and spawning stages are restricted to the period January to August, which indicates that the reproductive cycle of *M. squalida* in this locality seems to be seasonal. This lagoon is considered as a temperate geographic zone (Briggs 1974), whereas the Gulf of California is regarded as a tropical-subtropical transition zone (Hendrickx et al. 2005) and Bahía de Zihuatanejo, a tropical one (Briggs 1974). Differences in the reproductive pattern of any given species are known to occur along a latitudinal range, given that critical temperatures (cold or warm) occur in different months or prevail all the year round, facilitating a continuous reproduction (Hesselman et al. 1989). The earlier mentioned coincides with reports by Porter (1964) and Hesselman et al. (1989), who mention that the differences in the reproductive cycle among various populations seem to result from phenotypical responses to variations in environmental conditions, mainly food availability and temperature. To this respect, Baqueiro and Aldana (2000) state that some mollusc species display different gonad-recovery and spawning patterns associated with the microenvironmental conditions of their habitat.

Furthermore, this study revealed that the mean oocyte diameter of *M. squalida* living in the Ojo de Liebre lagoon was larger (30.6–45.2 μm) than the one reported by Quiñones-Arreola (2003) for *M. squalida* living in Bahía Juncalito, Gulf of California (25–40 μm). Oocyte growth depends on an adequate energy supply available for gametogenesis (Barber & Blake 1983). The availability of enough energy depends on both, food availability and the animal's metabolic rate, which to some extent is influenced by environmental temperature (Barber & Blake 1983). As mentioned earlier, food availability is high all the year round in Bahía Jun-

calito, which should favor a larger oocyte size, something that does not occur. This could be explained assuming that the metabolic rate in Bahía Juncalito might be higher than in Ojo de Liebre, given that temperature in the former is 5 °C higher (Quiñones-Arreola 2003). Additionally, the constant oocyte production (continuous reproductive cycle) in Bahía Juncalito involves more accelerated periods of gonad recovery and, consequently, smaller oocytes compared with oocytes from Ojo de Liebre are produced. For its part, food is not abundant in the Ojo de Liebre lagoon but there is a marked resting period, which would favor nutrient accumulation. Afterwards, nutrients would be available for gonad ripening, favoring a larger oocyte size.

This study found that the sex ratio in the population studied was 1:1. This finding coincides with reports for this same species in other localities (Table 2). This indicates that sex ratio is a species-specific characteristic unaffected by environmental conditions. Villalejo-Fuerte et al. (2000) infer, from a 1:1 sex ratio, that mortality in *M. squalida* (either natural or by fishing) does not differ between sexes, that no sexual dimorphism occurs in terms of size (because clams are caught only in the case of large specimens), and that growth rate seems to be similar for males and females. Nonetheless, further research is required to confirm the above.

As regards the size at spawning of *M. squalida* (92 mm SL) no comparisons are possible, given that no background information is available. However, smaller spawning organisms (42–50 mm SL) were reported in Bahía Concepción (Villalejo-Fuerte et al. 1996a), which are even below the smallest size reported in this study for a spawning organism (64 mm SL). According to the earlier mentioned, the size at spawning in Ojo de Liebre might be overestimated in this study. To corroborate this hypothesis, further research is required including smaller organisms.

ACKNOWLEDGMENTS

ABSTRACT Reliable banding techniques are a major necessity for the genetic research in marine bivalves. Restriction enzyme banding (HaeIII) was performed, in this study, on chromosomes of two commercially important species of veneroid bivalves: the clam *Ruditapes decussatus* (Adams and Reeve) and the cockle *Cerastoderma edule*. Identification of the nineteen individual chromosome pairs was obtained for both species. The cytogenetic studies made in marine molluscs have recently experienced a very fast development caused by the introduction of new molecular techniques mainly fluorescence *in situ* hybridization (FISH). Recently it has been shown in mammalian chromosomes that restriction enzyme banding is compatible with FISH, allowing simultaneous banding, and consequent accurate identification of the localization of the probes and unambiguously identification of the chromosome(s) carrier(s). As far as we know this is the first RE-banding obtained in karyotypes of veneroid species. The application of restriction enzyme chromosome banding in veneroids are diverse and this study can constitute a fundamental step for future gene mapping on this commercially important group of bivalves and could offer a new approach to specific problems in veneroid taxonomy and genetics.

KEY WORDS: *Cerastoderma edule*, chromosome banding, *in situ* restriction enzyme banding, *Ruditapes decussatus*, veneroid

INTRODUCTION

Cytogenetic investigations in veneroid and marine bivalves in general were first mainly concerned with data on chromosome number and gross morphology. Later, morphometric analysis of karyotypes provided characterization of chromosome morphology based on centromeric position. Afterwards, the application of differential staining techniques such as Ag-NORs for nucleolar organizer regions, C-banding for heterochromatin or G-banding for individual chromosome identification allowed the identification of specific chromosome pairs in the karyotypes of bivalve species (see Thiriou-Quévreux 2002, for review).

In the last 20 years, the introduction of new molecular techniques essentially fluorescence *in situ* hybridization (FISH) allowed a significant development in the cytogenetic studies made in marine molluscs. However the classical banding techniques such as G-, R- or Q-banding used for individual chromosomal identification, are not compatible with FISH. In fact these bandings are often lost during the *in situ* hybridization procedure even following refixation using relatively low temperatures and short times for denaturation (Chaves et al. 2002) making difficult the accurate chromosomal localization of the probes and the identification of the chromosome(s) carrier(s).

In several recent studies on the application of the FISH technique to marine bivalves, and although these applications were successful in obtaining positive signal(s) of hybridization, a difficulty in the unambiguous identification of the exact chromosomes carrier of the probes was encountered, except on the cases of localization of the probes on the largest or smallest chromosome pairs, which can be easily distinguished by their highly differentiated size. Chromosome carriers could only be barely identified based on their size and centromeric index, not by means of individual chromosome banding identification (e.g., Clabby et al. 1996,

Zhang et al. 1999, Insua et al. 1999, Gonzalez-Tizon et al. 2000, Xu et al. 2001, Wang & Guo. 2004, Hurtado & Pasantes 2005), which unfortunately limits the extent of the potential of this technique.

In situ digestion with restriction endonucleases (REs), which cleave DNA at specific target sequences, has been shown to produce consistent banding patterns in fixed mammalian and insect chromosomes and more recently has been successfully applied to mussels (Martinez-Lage et al. 1994), scallops (Gajardo et al. 2002) and oysters (Leitão et al. 2004, Bouilly et al. 2005, Cross et al. 2005). In all cases, specific longitudinal chromosomal banding patterns were obtained after digestion with REs, allowing the individual identification of all chromosome pairs and the establishment of precise karyotypes. This technique has also been applied in a chromosomal evolution study within the Ostreidae family (Leitão et al. 2004).

RE banding presents a major advantage, in fact it has been recently shown in mammals that restriction enzyme banding is compatible with FISH (Chaves et al. 2002). Moreover, the combined use of different REs can also be useful in the detection of different classes of heterochromatin not revealed by standard banding techniques.

Genetic studies of commercially important marine bivalves have considerably increased in recent years, becoming crucial for the development in aquaculture. The harvesting of veneroid bivalve species has been an important component of European and Northern Africa fisheries since ancient times. The clam *Ruditapes decussatus* and the cockle *Cerastoderma edule* are of great socio-economic importance in Europe and are widely distributed along the coastline. The culture of these bivalve molluscs, mainly the culture of the clam, *R. decussatus*, represents a major fraction of the molluscan mariculture in Portugal with over 10,000 people directly or indirectly involved in this activity (Ruano 1997, Ruano & Cachola 1986).

Clam species of the subfamily Tapetinae (see Fischer-Piette &

*Corresponding author. E-mail: aleitao@ipimar.pt

Métivier 1971, and Partridge, 1977 for taxonomic revision) are of considerable commercial importance but very little has been published on their basic genetics. Only 2 (Wilkins & Mathers 1974, Walne & Wood 1975) of the 225 references cited by Partridge (1977) on *R. decussatus*, concern genetics. Since 1975, genetic studies on the genus *Ruditapes* remain scarce (Borsa & Thiriot-Quiévreux 1990). In cytogenetics concerns, the studies consisted only of chromosome number determination of *R. phillipinarum* and *R. decussatus* ($2n = 38$) (Gérard 1978), triploidy induction in *R. phillipinarum* (Beaumont & Contaris 1988, Goslin & Nolan 1989), and only standard karyotype characterization with intragenus comparison of *R. phillipinarum*, *R. aureus* and *R. decussatus* (Borsa & Thiriot-Quiévreux 1990).

Very little karyological data have been published until now on *Cerastoderma*. A chromosome complement of $2n = 38$ has been reported in *C. edule* and *C. glaucum* (Koulman & Wolff 1977). Only standard karyotype has been described in an Atlantic population of *C. edule* (Insua & Thiriot-Quiévreux 1992) and standard karyotype, and the location of the nucleolar organizer regions were described from Baltic and Mediterranean populations of *C. glaucum* (Thiriot-Quiévreux & Wolowicz 1996). FISH was successfully applied in *C. edule* for the study of the 5S rDNA repeated unit (Insua et al. 1999).

However, up till now, no banding technique, which allows the individual identification of all chromosome pairs was applied to any of these species. The unambiguous identification of all individual chromosome pairs is essential for: (1) the establishment of the precise karyotype of these species; (2) chromosome evolution studies (through the study of possible fissions, translocations, and deletions); (3) aneuploidy studies and (4) the precise localization of *in situ* hybridization probes, because the chromosomes pairs carrying the probes cannot be accurately determined without unambiguous identification of all chromosome pairs.

To fulfill this gap in these two veneroid species, we applied in this study the restriction enzyme banding technique to fixed metaphase chromosomes of *R. decussatus* (Veneridae) and *C. edule* (Cardiidae).

MATERIALS AND METHODS

Biological Material

Specimens of *R. decussatus* were intertidally collected at Lameirão (Ria Formosa lagoon, south of Portugal) and specimens of *C. edule* were intertidally collected at Almargem (Ria Formosa lagoon, south of Portugal). Before processing, the animals of both species were acclimated at the IPIMAR-Culture Molluscs Experimental Station Hatchery for one week.

Chromosome Preparation

Whole juvenile animals (ca. 1.5-cm length) were incubated for 7 h in a 0.005% solution of colchicine in seawater. Then the gills were dissected and treated for 30 min in 0.9% sodium citrate in distilled water. The material was fixed in a freshly prepared mixture of absolute alcohol and acetic acid (3:1) with three changes of 20 min each. Fixed pieces of gill from each individual were dissociated in 50% acetic acid with distilled water solution. Slides were prepared following an air-drying technique (Thiriot-Quiévreux & Ayraud 1982). The slides were kept at -20°C until further used.

In situ Restriction Endonuclease Digestion

Slides were aged during 6 h, in a dry incubator at 65°C , before the restriction endonuclease treatment. The restriction enzyme used: HaeIII (GG/CC) was diluted in the buffer indicated by the manufacturer (Invitrogen, Life Technologies), and final concentrations of 30 U were obtained per 100 μL (following Leitão et al. 2004). The 100- μL of this solution was placed on each slide and covered with coverslips. These slides were incubated in a humid chamber for 16 h at 37°C . Control slides were submitted to the same treatment as described earlier in this study but incubated only with buffer. The slides were then washed in distilled water, air dried and stained with Giemsa (1% solution, diluted in phosphate buffer at pH 6.8).

Microscopy and Image Processing

Images of metaphases of *R. decussatus* and *C. edule* banded with the restriction endonuclease HaeIII were acquired with a CCD camera (Axiocam, ZEISS) coupled to a ZEISS Axioplan 2 Imaging microscope. Digitized photos were printed from Adobe Photoshop (version 5.0) using only contrast optimization functions that affected the whole of the image.

Karyotype Organization

The karyotypes of the banded metaphases were organized based on the length, centromeric position and RE-banding pattern. Because we are working with somatic tissues, we had to use many animals to obtain a sufficient number of mitoses. A total of 38 RE-banded karyotypes were examined for *R. decussatus* and 42 for *C. edule*.

RESULTS

The diploid complement of both *R. decussatus* and *C. edule* was $2n = 38$, and the proportion of the different morphometric types of chromosomes observed in both species was similar to the one observed in previously published results, 6 metacentric, 3 submetacentric and 10 subtelocentric pairs for *R. decussatus* (Borsa & Thiriot-Quiévreux 1990) and 12 submetacentric, 4 subtelocentric and 3 telocentric for *C. edule* (Insua & Thiriot-Quiévreux 1992).

The RE (HaeIII) tested yield specific banding pattern in the 38 RE-banded karyotypes examined of *R. decussatus* and the 42 of *C. edule*. Moreover, the banding patterns were consistent between members of homologous chromosome pairs. The *in situ* RE experiment was compared with control treatment on slides from both species. Control slides were tested with the same treatment as the *in situ* restriction banding slides, but incubated only with buffer. In both cases, there was no banding pattern induced in the chromosomes, and all chromosomes incubated (from both species), with only buffer from HaeIII showed a Giemsa standard staining.

Examples of banded metaphases with HaeIII are present in Figure 1 for *R. decussatus* (Fig. 1a) and *C. edule* (Fig. 1b). Karyotypes with consistent banding pattern between homologous pairs are shown in Figure 2 for *R. decussatus* (Fig. 2a) and *C. edule* (Fig. 2b). All results are assembled and summarized in Figures 3 and 4, which show the haploid distribution of HaeIII chromosomal bands in the two species. HaeIII produced a banding pattern along the length of each chromosome (Figs. 3 and 4). The restriction banding produced was adequate for the single identification of all chromosomes for both species and organization of their respective

Figure 1. Examples of banded metaphases with the RE HaeIII: Figure 1a, metaphase of *R. decussatus*; Figure 1b, metaphase of *C. edule*. Scale bar = 5 μ m

karyotypes (Figs. 2, 3 and 4). Interstitial, centromeric and telomeric bands were observed along the chromosomes of both species.

In the right side of each column of Figures 3 (for *R. decussatus*) and 4 (for *C. edule*) is shown a schematic representation of the *in situ* restriction banding patterns obtained for each species.

DISCUSSION

The diploid chromosome number of $2n = 38$ is confirmed in both *R. decussatus* and *C. edule* and appears to be the modal number of the Veneridae and Cardiidae families (Nakamura 1985, Corni & Trentini 1986), and it is also common among the super-order Veneroida (Thiriot-Quievreux et al. 1987).

The application, for the first time, of the RE HaeIII to the chromosomes of the clam *R. decussatus* and the cockle *C. edule* produced specific banding patterns and allowed the unambiguous

individual identification of all the chromosome pairs making possible the preparation of accurate karyotypes and their respective ideograms (Figs. 1–4). Therefore, this technique has demonstrated to be a reliable technique and more prompt (compared with conventional banding techniques) for veneroid chromosome banding.

For the construction of the ideograms, we only described the presence of the bands and each band's relative position; the intensity of the bands was not considered. The intensity of the bands in the RE treatments seems to be related to the type of counterstain used (e.g., Giemsa or fluorochroms) (Gonsálvez et al. 1991). Several authors demonstrate that the loss of DNA after a RE digestion can increase the capacity of the stain to bind to a specific chromosome region (Gonsálvez et al. 1991, Nieddu et al. 1999). Therefore, it seemed reasonable not to consider the intensity of the bands in the construction of ideograms but only their presence and position.

The *in situ* restriction banding technique, applied here to both

Figure 3. Haploid distribution of the chromosomal bands (left side of each column) and schematic representation of the *in situ* restriction banding patterns (right side of each column) obtained for the RE HaeIII in *R. decussatus*.

species, presents a major advantage, that can be used simultaneously with FISH techniques (Chaves et al. 2002), demanding only one round of observation and minimal extra preparation steps. Consequently, the *in situ* restriction banding technique will facili-

tate physical mapping in this group of bivalves, besides being compatible with more traditional banding techniques.

Furthermore because tissue culture protocols are not yet available in marine bivalves, the chromosomes are prepared directly

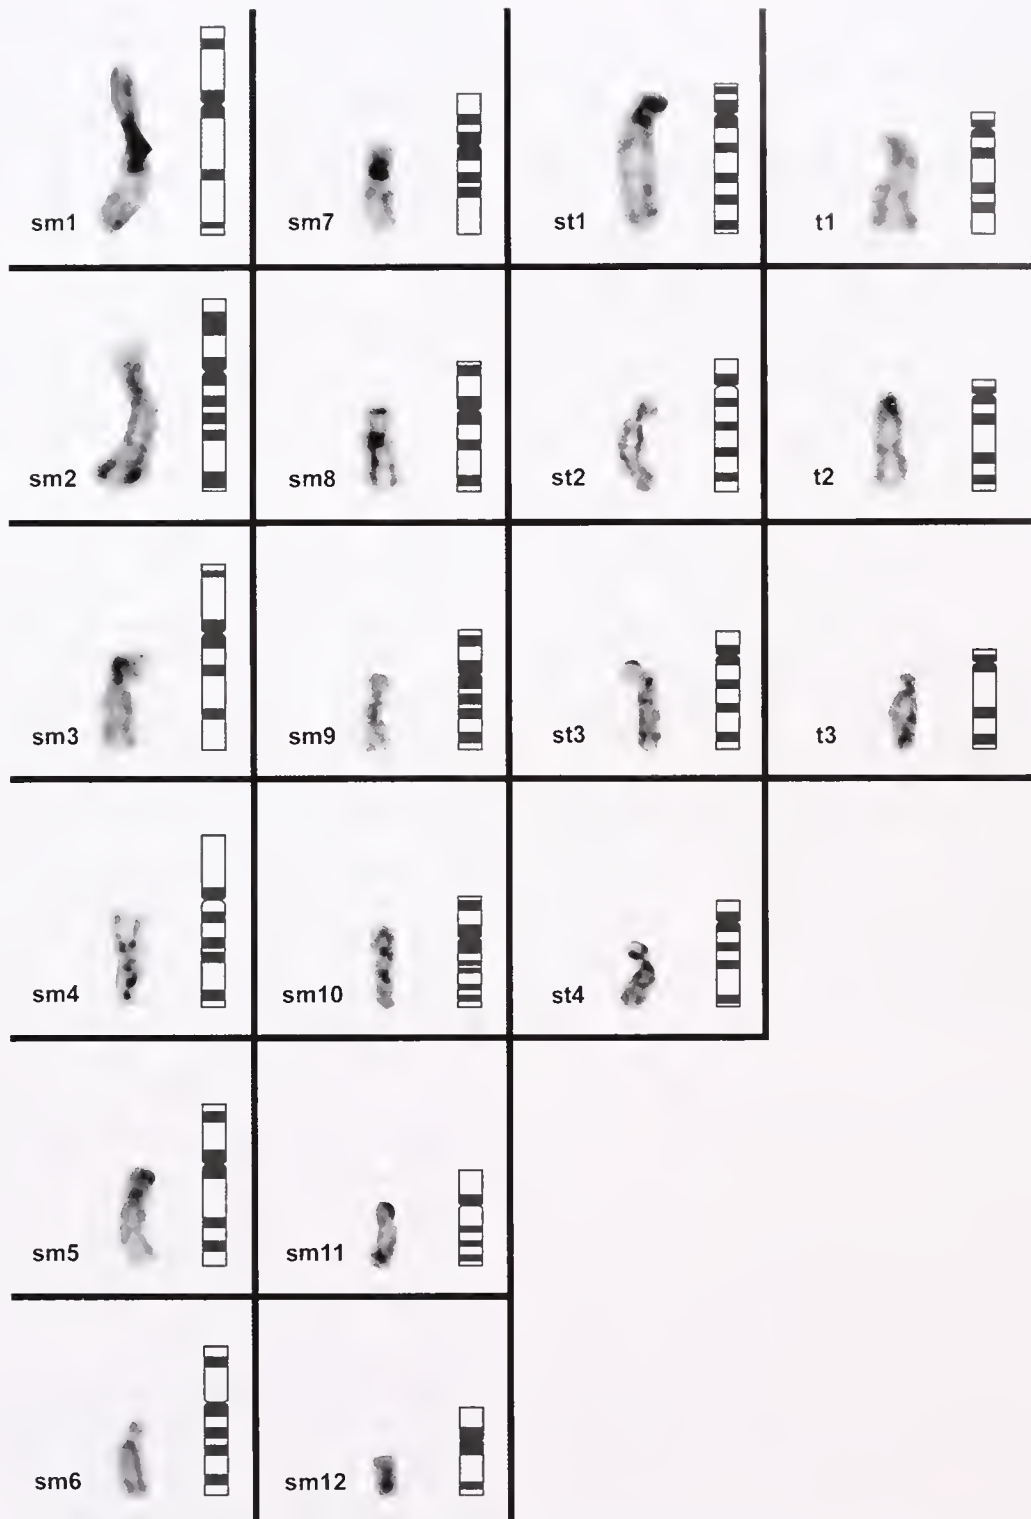

Figure 4. Haploid distribution of the chromosomal bands (left side of each column) and schematic representation of the *in situ* restriction banding patterns (right side of each column) obtained for the RE Hae III in *C. edule*.

from the animals and are of poor morphology. The *in situ* restriction banding technique better preserves the morphology of the chromosomes (compared with other conventional banding methods), representing an additional advantage for the identification of

veneroid chromosomes, when using further techniques such as FISH or C-banding (Chaves et al. 2002).

The use of the RE-banding technique can be very useful in several studies of economic or ecological importance within this

group of veneroid bivalves. For instance: (a) in evolution of chromosome and karyotypes; (b) can also provide a rapid method for the identification of the missing chromosomes in aneuploidy situations, for which a negative correlation with the growth rate was put in evidence in other bivalve species (Leitão et al. 2001) and (c) for the study of the impact of contaminants (anthropogenic compounds, and so forth) on the genetic patrimony of veneroids (through the identification of possible neoplasias, missing chromosomes, deletions, translocations and so forth). This last application is far more important because the clam *R. decussatus* has been recently proposed as a potential bio-indicator species in areas where mussels are not available (Bebianno et al. 2004). In fact clams are appropriate organisms for monitoring because they are sedentary filter feeders that exhibit a high level of diversity at a large number of loci (Moraga et al. 2002). Moreover, the tissue most currently

used for cytogenetic analysis is from the gills, which is one of the most "interesting" tissues from the ecotoxicological point of view (Bebianno et al. 2004).

This study shows that the applications of restriction enzyme chromosome banding in veneroids are diverse and can constitute a fundamental step in gene mapping in this commercially important group of bivalves and could offer a new approach to specific problems in veneroid taxonomy and genetics.

THE HYPOXIC TOLERANCE OF THE PROTOBRANCH BIVALVE *NUCULA SULCATA* BRONN

SEBASTIAN P. HOLMES^{1,2} AND NICOLA MILLER¹

¹Port Erin Marine Laboratory, Port Erin, Isle of Man, IM9 6JA, British Isles, ²The Ministry of Fisheries, PO Box 1020, 101-103 The Terrace, Wellington, New Zealand

ABSTRACT Examination of the hypoxic tolerance of *Nucula sulcata* determined that the mean survival time under hypoxia was 9.57 d with a maximum longevity of 30 d. Comparison between the three species, *N. sulcata*, *N. nitidosa*, and *N. nucleus* reveals that *N. sulcata* is the most tolerant of hypoxia followed by *N. nucleus* and *N. nitidosa*. It is suggested that the hypoxic tolerance of the species is a reflection of the normal habitat they occupy.

KEY WORDS: environmental tolerance, hypoxia, *Nucula sulcata*, protobranch, adaptation

INTRODUCTION

The protobranch bivalves, *Nucula sulcata*, *N. nucleus*, and *N. nitidosa* are three of the five species of Nuculidae commonly found in soft sediments in British waters. Their distribution has been linked to particular sediment types, with *N. nitidosa* inhabiting muddy sand; *N. nucleus*, muddy gravels; and *N. sulcata* sandy mud/mud, hence in most locations only one of the species is found. This has led to the suggestion that the distribution of the species is determined, in part, by their physiology. For example, *N. nitidosa* and *N. nucleus* have been shown to have different metabolic rates, which can be related to their particular habitats (Holmes et al. 2002, see also Wilson & Davies 1984, Creutzberg 1986).

One important adaptation between the three species, that may affect their distribution, is their tolerance to hypoxia. With regard to *N. nitidosa* and *N. nucleus*, it has been determined that *N. nucleus* has a hypoxic tolerance ~3 times that of *N. nitidosa*, which may be reflected in its occupation of muddier habitats and hence an increase in its likelihood of experiencing hypoxic events (Holmes et al. 2002). The only observation pertaining to the hypoxic tolerance of *N. sulcata* is effectively anecdotal in nature (Taylor et al. 1995) with no replication and/or independence of experimental design, as is the case for most hypoxic tolerance studies (see Dries & Theede 1974 and Zwaan et al. 2001 for examples). The aim of this study, was to measure the hypoxic tolerance of *N. sulcata*, using an experimentally robust design and directly compare these results with those obtained for *N. nitidosa* and *N. nucleus* in earlier years, previously published elsewhere (Holmes et al. 2002), under the hypothesis that the hypoxic tolerance of the species should increase as the mud content of their habitat increases (i.e. as the likelihood of the frequency of hypoxic events increases).

MATERIALS AND METHODS

Bivalves, *N. sulcata*, were collected in the mouth of Gullmarsfjord, off Gäsö island (58°14.19'E 11°26.36'N) in 2001, using an Agassiz trawl, and taken to Kristineberg Marine Research Station, Fiskerbackskil, Sweden where all experiments were carried out. Once at the laboratory, the specimens were left for 5 days in sediment to acclimatize, in running seawater (~10°C). Measurement of the hypoxic tolerance of *N. sulcata* was made as follows (the measurement of the hypoxic tolerance of *N. nitidosa* and *N. nucleus* was made in an identical fashion and is reported elsewhere [Holmes et al., 2002]). Ten liters of autoclaved filtered (0.2 µm) seawater (10°C) was vigorously bubbled with filtered (0.2 µm) N₂, in a semi-enclosed vessel, for 6 h prior to the start of the

experiment (i.e., to ensure that the seawater contained as little oxygen as possible). One hundred and twenty, 9-mL (nominal) bottles were then filled with the seawater and a randomly selected animal placed into each. Ninety of the bottles were then capped, ensuring that the bottle remained under the surface of the water at all times (treatment animals), and the remaining 30 bottles were left uncapped (control animals). In addition, 35 bottles were filled with seawater and the bottles capped (water control). Five of these bottles were immediately analyzed for their oxygen content (Holmes et al. 2002). All of the bottles were placed together under a 12 h day/night cycle and maintained at 10°C for the duration of the experiment.

Every day, the treatment and control animals were inspected, individually, to ascertain whether they were alive. If an animal was found to be dead, it was removed from the experiment and its death recorded along with its shell height, width, length, whole dry weight, flesh dry weight, and the oxygen concentration of the water. Every 5 days, from the start of the experiment, 5 randomly selected water controls were removed and the oxygen concentration determined. The end of the experiment was determined by the death of all of the animals. It should be noted that, the measurements of hypoxic tolerance made here will inherently include other confounding factors (e.g., starvation) that will result in an under, rather than over estimation.

RESULTS AND DISCUSSION

The mean oxygen concentration of the seawater at the start of the experiment ± standard error (SE) was 1.56 ± 0.13 mL O₂ l⁻¹ and hence the seawater can be regarded as hypoxic at the start of the experiment, see Figure 1 (Diaz & Rosenberg 1995). Comparison of the control water oxygen concentration during the experiment, using ANOVA, revealed no differences. Linear regression of the lifetime of *N. sulcata* versus the mean oxygen concentration of the water samples, at the time of death, produced a statistically significant regression. The O₂ concentration of the water for the treatment animals dropped over time as they respired, leading to their eventual death (Fig. 1). Analysis of the number of animals dying per day, against the mean O₂ concentration for the animals that died that day, using Spearman's rho, to determine if there was a threshold O₂ concentration lower than that at the start of the experiment that caused death, produced no statistically significant correlation; the initial O₂ concentration of the water was sufficient without any further reduction in its oxygen concentration to cause death by hypoxia. Correlation, using Spearman's rho, of the shell length, height, width, whole body dry weight, and dry flesh weight data to the survival data, failed to produce any statistically significant correlations (i.e. death caused by hypoxia does not seem to be related to body size).

The mean and standard error of the oxygen concentration of the control and treatment samples compared with the number of *N. sulcata* that have died on each day. □, Mean oxygen concentration of the control samples; ○, mean oxygen concentration of the treatment samples; ●, number of treatment animals that have died; ■, number of control animals that have died; calculated regression line (mean oxygen concentration treatment samples).

Figure 2. Comparison between the death rate (cumulative percentage) of *N. sulcata*, *N. nucleus*, and *N. nitidosa* treatments and controls. — (A) Treatment *N. sulcata*; --- (B) Control *N. sulcata*; — (C) Treatment *N. nucleus*; --- (D) Control *N. nucleus*; - - - (E) Treatment *N. nitidosa*; ····· (F) Control *N. nitidosa*.

Analysis of the survival data, using the Kaplan-Meier procedure with log rank comparisons (Klein & Moeschberger 1998), determined that survival rate of the *N. sulcata* treatment animals was different from that of the *N. sulcata* control animals ($P = 0.003$, Fig. 2). The mean \pm SE survival time for the treatment animals was 9.57 ± 0.68 d (median = 7 d, $LT_{50} = 7$ d) and 14.45 ± 1.27 d (median = 13 d, $LT_{50} = 13$ d) for the control animals (Fig. 2). For the treatment and control animal the maximum longevity was 30 d. Note, 13 treatment animals and one control animal bottles were broken during the experimental period and hence were excluded from the analysis. Comparison between the previously published survival data for *N. nitidosa* and *N. nucleus* with the *N. sulcata* data, again using the Kaplan-Meier procedure with log rank comparisons, revealed that survival rates for all species were different from each other ($P \leq 0.003$) (Fig. 2). That is, *N. nitidosa* (mean \pm SE survival time = 3.53 ± 0.28 d) was most susceptible to death by hypoxia followed by *N. nucleus* (mean \pm SE survival time = 7.72 ± 0.21 d) and then by *N. sulcata*. In effect, *N. sulcata* has a hypoxic tolerance ~ 1.25 times greater than that of *N. nucleus* and 5 times that of *N. nitidosa*. In terms, of total longevity (i.e., the time taken for all animals to die), *N. sulcata* has a maximum longevity of approximately twice that of *N. nucleus* (longevity ~ 15 d) and approximately three times that of *N. nitidosa*. The maximum survival time recorded for *N. sulcata* (30 d) is less than that recorded, but of the same order, for *Corbula gibba* (34 + d), which occupies a similar habitat (Holmes & Miller 2006).

With regard to the existing observation within the literature as to the hypoxic tolerance of *N. sulcata* ($LT_{50} = 14$ d and longevity = 21 d) (Taylor et al. 1995) the values reported here are different. In part, arising from the different methodologies used but also from the more robust experimental design adopted. Irrespective of the cause of the difference, the results presented here for *N. sulcata* are directly comparable with those recorded for *N. nitidosa* and *N. nucleus*, revealing as hypothesized that the hypoxic tolerance of the three species can be linked to the habitat they normally occupy. In terms of comparison with other nuculides, *N. tenuis* has been recorded as having a maximal longevity of 17 d (Moore 1931), and there are no observations for *N. hanleyi*. If the hypothesis substantiated were correct, then it would be interesting to measure the hypoxic tolerance of *N. hanleyi*, which should be approximately equal to or lower than that of *N. nitidosa* and *N. hanleyi* occupying sandy sediments with a high oxygen concentration. Similarly, the hypothesis could be expanded to a range of bivalve species, for example *Abra alba*, which inhabits sandy mud and has a much lower hypoxic tolerance than *A. elliptica* occupying muddy/gravelly sands (Dries & Theede 1974). The importance in individual, nonobservable, adaptations between closely related species in determining their distribution patterns has been often overlooked in sublittoral benthic ecology. However, any experiments performed to attempt to discern adaptational differences need to be done in an experimentally robust manner, with independent observations, such that correct cross comparisons between species can be attained.

REPRODUCTIVE CYCLE OF THE RAZOR CLAM *SOLEN MARGINATUS* (PULTENEY 1799) IN SPAIN: A COMPARATIVE STUDY IN THREE DIFFERENT LOCATIONS

ANTONIO REMACHA-TRIVIÑO* AND NURIA ANADÓN

Departamento de Biología de Organismos y Sistemas, Área de Zoología, Universidad de Oviedo, c/Catedrático Rodrigo Uría s/n, E-33071 Oviedo, Asturias, Spain

ABSTRACT The reproductive cycle of the razor clam *Solen marginatus* (Pulteney 1799) was studied in three different locations of Spain. Sampling was performed in the natural beds of: Eo Estuary (NW Spain) in 1994 to 1995, Santander Bay (N Spain) in 1998 to 1999 and Terrón Estuary (SW Spain) in 1999. In Eo, Santander and Terrón, respectively: phase 0 (resting stage) occurred in July to August, September to October and August to September, phase I (proliferation of gonias) happened in: August to October, October to December and September to November, phase II (gametogenesis) was developed in November to April, January to May and December to April and phase III (reproduction) took place in: May to June, June to August and May to July. Two new approaches oriented to the fast monitoring of the gametogenic cycle of the species based on sequential mean drained soft parts weights obtained by simulation and on the macroscopic observation of the gonad are presented.

KEY WORDS: bivalves, *Solenidae*, *Solen*, reproduction

INTRODUCTION

The superfamily Solenacea is an infaunal soft bottom dwelling bivalve group consisting of the two marine families Solenidae and Pharidae (=Cultellidae, Cosel 1993).

Razor clams are bivalves whose commercial demand has notably increased in Spain in recent years (Remacha-Triviño 1996). As a consequence of this, the natural beds of these species can be subjected to overexploitation.

Solen marginatus (Pulteney, 1799) is a representative intertidal bivalve of the Spanish coasts. Accordingly, this species is distributed along the west Mediterranean Sea and Atlantic Ocean from Britain to Mauritania (Cosel 1993), comprising all of Spain's coasts. This species can be considered the third most important commercial razor clam of Spain after *Ensis arcuatus* and *E. siliqua*.

Previous references dealing with the reproductive cycle of *S. marginatus* are: Rodríguez-MoscOSO et al. (1996), Gaspar (1996), Remacha-Triviño (1996), Tirado et al. (2002), Remacha-Triviño (2002), Martínez (2002) and López et al. (2005). However, there are not precedent studies dealing with the reproductive cycle of this species either in Santander Bay or in Terrón Estuary, as well as a comparative survey among these three locations.

Two of the most important strategies oriented to improve the management of the marine medium are a more rational exploitation of the natural resources and the application of aquaculture as an instrument aimed to increase the production of commercial species. Alternatively, artificial culture constitutes a way to compensate the lack of other species, which, because of overharvesting continue to diminish. A thorough comprehension of the reproductive cycle provides: (1) the establishment of close seasons in keeping with the spawning periods; (2) optimization of the breeding conditions oriented towards improving the quality of commercial exploitation and, in a more general framework, with the purpose of expanding sustained development and (3) the genetic selection of varieties of a higher reproductive efficiency and more resistant to pathologies or stress conditions related to reproduction.

The purpose of this study is to draw a comparison among the reproductive cycle of *S. marginatus* in three separate locations of

Spain and to present two new approaches oriented to the fast monitoring of the gametogenic cycle of this species, based on the macroscopic observation of the gonads and on sequential mean drained soft parts weights obtained by simulation. In this way, the understanding of the reproductive biology of *S. marginatus* is improved, making this information relevant for promoting a future extensive culture for this species, oriented to satisfy its commercial demand and to guarantee the conservation of its natural beds.

MATERIALS AND METHODS

Samples of 50–65 razor clams were collected intertidally in 3 different locations including the Eo Estuary (Asturias, NW Spain), Santander Bay (Cantabria, N Spain) and Terrón Estuary (Huelva, SW Spain) (Fig. 1). Specimens from Eo Estuary were collected from June 1994 to May 1995. Specimens from Santander Bay were collected from October 1998 to September 1999. Specimens from Terrón Estuary were collected from January 1999 to December 1999.

Live razor clams were transported to the Invertebrates Laboratory of the Department of Biology of Organisms and Systems (University of Oviedo, Asturias, Spain). Caliper shell lengths and drained weights were measured to the closest 0.01 mm and g, respectively. Next, animals were fixed in 10% formalin in seawater and the following procedures were applied.

Histological Techniques

Twelve animals (six males and six females) per month were used for histology. A sample of approximately 10 × 5 mm visceral mass was dissected from the internal ventral portion of each foot (Remacha-Triviño 1996), starting from a fixed point (i.e., left square) chosen at random, dehydrated in graded ethanols and embedded in paraffin according to Durfort (1993). Seven micrometers serial sections were obtained and stained routinely with Hematoxylin-Eosin. Stages of the reproductive cycle were classified under the maturity scale of Chipperfield (1953) and Lubet (1959) widely used by different authors (e.g., see Villalba 1995), which comprises the following phases: 0 (resting stage), I (proliferation of gonias), II (gametogenesis) and III (reproduction) of subphases: III A (ripeness), III B (early spawning), III C (restoration) and III D (late spawning).

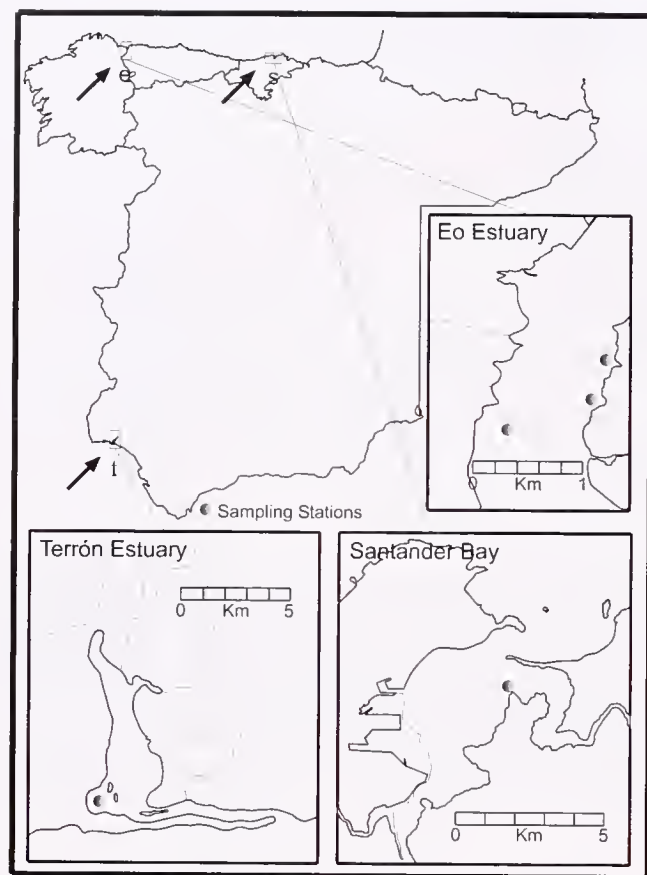

Figure 1. Map of western Spain (excluding Portugal). Arrows show the relative locations of: Eo Estuary (NW Spain), Santander Bay (N Spain) and Terrón Estuary (SW Spain). Abbreviations: e, Eo Estuary; s, Santander Bay; t, Terrón Estuary.

Macroscopic Observation of Gonads

Feet were dissected ventrally along the line of intersection with the sagittal plane. Gonads were classified in relation to their macroscopic appearance under the maturity scale used for histology.

Sequential Mean Total Drained Weights

Sequential mean total drained weights were estimated in each month from the arithmetic progression of shell lengths restricted to sizes between 65–130 mm. $\{a_L\} = 5 \cdot (12 + L) \nabla_{a_L} [65,130]$, whose elements were obtained by simulation from their corresponding monthly regressions $\log W | \log L$.

RESULTS

Extension of the Gonad

The extension of the gonad of *Solen marginatus* is restricted to the internal portion of the foot where it is enclosed permanently, even in the periods of maximal gonadal development. Follicles line the internal surface of the pedal sinus, adjacent muscular layers and parts of viscerae enclosed therein and facing its lumen. The interfollicular connective tissue, common in most bivalve species, is absent.

Histology

Phase 0 (Resting Stage)

Sex Indistinguishable. Spread of follicular tissue limited to minor areas located among the peripheral muscular bundles of the

pedal sinus (Fig. 2A). Gonads were not observed in some of the specimens. Hemocytes surrounding the unabsorbed necrotic masses derived from the precedent subphase III D (see below) were frequent. Gametogenic elements reduced to reservoirs of stem cells (Fig. 2B to C) of characteristics: (1) ellipsoidal, spheroidal or polygonal shapes; (2) basophilic to lightly acidophilic staining affinity; (3) bigger size than gonias; (4) high nucleocytoplasmic quotient and (5) boundary cytoplasm-nucleus diffuse.

Phase I (Proliferation of Gonias)

Intense mitotic activity and spread of gonias, which proliferated by forming disperse poolings of cells located around the internal muscle layers and visceral mass of the foot (Fig. 2D to G). Clusters of gonias were enclosed within the follicular cells to constitute the primary follicles. Oogonias and spermatogonias showed common morphological features. Both cells were roughly ellipsoidal, displaying neutrophil cytoplasm, slightly acidophilic nuclei, clear boundaries nucleus-cytoplasm and similar sizes, ranging between 3 and 13 μm in diameter (Fig. 2E, G, L).

Phase II (Gametogenesis)

In females, the first previtellogenic oocytes were observed at the beginning of this phase. When compared with oogonias, the former exhibited cytoplasm and nuclei with a similar degree of neutrophilia and a diffuse boundary cytoplasm-nucleus with no visible nucleolus. Some of these first oocytes remained free in the follicular lumen, with no apparent point of attachment to the follicular wall (Fig. 2J). In posterior stages of oogenesis, nuclear membrane and nucleolus became distinguishable and oocytes were found either attached to the follicle wall or free in the follicular lumen, but always connected to aerial follicular cells in the latter case (Fig. 2H, I). In males, spermatocytes were the predominant cellular type in early spermatogenesis (Fig. 2K). These were roughly spheroidal cells of approximately 5 μm in diameter, deep basophilic nuclei and a high nucleocytoplasmic quotient. In posterior phases of early gametogenesis, the gonad gradually invaded the internal muscular and fibrous connective surfaces of the pedal sinus and free portions of the viscerae—digestive gland and gut—enclosed within the foot, with the exception of some concrete areas lined exclusively with integumentary musculature. In winter, the progress of the gametogenesis was generally slow or in recession. Late gametogenesis was mainly developed through spring. In females, oocytes nuclei tended to emigrate towards a more apical position within the cytoplasm, whereas the longitudinal axis of the cells was used to reallocate radially towards the follicular lumen. Oocytes were generally attached to the follicular wall by means of stalks that were not as evident as in other bivalve species. Masses of basophilic clusters of atresic oocytes were frequent. In males, proliferation of spermatocytes was increased notably, a process simultaneous with the first manifest masses of spermatozoa. Male gonads were composed mainly of spermatocytes, spermatids and spermatozoa (Fig. 2L). Although spermatocytes continued to be the most frequent spermatogenic stage, densities of the other cellular types were augmented significantly. The first minor releases of gametes took place at the end of this phase.

Phase III (Reproduction)

Subphase III A (Ripeness): Gonads were deeply packed and full of gametes near emission. Follicles were extremely expanded. In most cases, the feet became so dilated that they were hardly

I: Detail of H showing the junctions of the oocytes to the follicular cells. J: Detail of H showing the first stages of the oocytes. K to L: Testis in phase II. M: Ovary in subphases III B and III C, simultaneously. N: Ovary in subphase III A. O: Ovary in subphase III D. P: Testis in subphases III A, III B and III C, simultaneously. Q: Testis in subphase III D. Abbreviations: c, tails of spermatozoa; sdp, spermatids and heads of spermatozoa; cm, stem cells; oc, oocytes; og, oögonias; se, spermatoocytes; sg, spermatogonias.

retractable. Atresic oocytes were less frequent than in phase II, as indicative of a probable mechanism of resorption. Mature oocytes were detached from the follicle wall, adopting a more spheroid

geometry turned to poliedric at highly packed areas (Fig. 2N). Males showed a significant predominance of spermatozoa mainly positioned at the center of the follicular lumen (Fig. 2P).

Subphase III B (Spawning): Phase of spawning was restricted to unspecific areas of the gonad, whose follicles were found to be partially evacuated because of the releases of gametes (Fig. 2M, P).

Subphase III C (Restoration): Intervals among consecutive spawnings were characterized by a restorative activity yielded to a highly variable pattern, depending on sex, number of precedent spawnings and duration of these previous periods of spawning. In females, restoration gave rise to follicles whose oocytes showed a major proportion of immature oocytes. Spreading of oögonias was also observed. In males, the follicles found in coexistence with follicles III A and III B, with no spaces in the lumen and without a predominance of spermatozoa, were classified under phase III C, although the pattern of restoration was not clearly observed in males (Fig. 2M, P).

Subphase III D (Last Emissions): Evacuation of all the potentially releasable gametes from the gonad generally happened after a succession of various minor spawnings plus a major one. Nevertheless, gonads examined after the major spawning showed follicles that were not completely evacuated, implying some minor releases after the major spawning to complete this process. In the evacuated follicles, elements of gametogenesis were reduced to small pools of gonias, stem cells and necrotic masses of residual oocytes. A strong parallel resorptive activity took place. Follicles were progressively drawn back down the fibromuscular tissues and reabsorbed later (Fig. 2O, Q). Groups of hemocytes were particularly numerous in this phase by forming aggregates of phagocytosis within the degenerating tissues.

Sequential ratios of phases of the reproductive cycles investigated are presented in Figures 3, 4, 5.

Macroscopic Level

Phases 0 and I. Gonad not observed macroscopically or reduced to a thin layer of hyaline tissue. Whitish areas corresponding to putative primordia of follicular tissue were detected occasionally over the internal surface of the pedal sinus (Fig. 6A to B). Phase II. Gonad clearly observed macroscopically, extending from discontinuous portions of the pedal sinus to almost all its inner surface area. Internal surface of the gonad mainly distributed in form of small transverse folds of tubular appearance. These folds were whitish in males and brownish in females (Fig. 6C to D). Subphases III A, III B and III C. Pedal sinus almost obliterated by gonad. Internal surface of gonad composed by bigger folds resem-

Figure 4. Sequential ratios of phases of the reproductive cycle of Santander Bay observed in histological sections. Abbreviations: 0, phase 0; I, phase I; II, phase II and III, phase III.

bling small sacs of fragmented surface in males and wavy surface in females (Fig. 6E to F). Subphase III D. (1) Early stage: Internal surface of gonad arranged in folds similar to the previous ones but less dimensioned. (2) Late stage: Gonadal arrangement analogous to phase II except for the inside of the tubular folds, which are covered in stains, as a probable consequence of the mechanism of resorption (Fig. 6G, H).

Mean Total Drained Weight

The sequential mean total drained weights of the different reproductive cycles investigated are shown in Figure 7.

DISCUSSION

Histology

The reproductive cycle of *Solen marginatus* fits the general pattern observed in other bivalves of temperate waters (i.e., annual cycle, seasonal phases, all the different phases cannot be found simultaneously) being analogous to: *Crassostrea virginica*, *Cerastoderma edule*, *C. glaucum*, *Mytilus edulis*, *M. galloprovincialis*, *Lithophaga lithophaga*, *Paphies australis* and *Venus striatula* (Loosanoff 1942, Lubet 1959, Ansell 1961, Boyden 1971, Galinou-Mitsoudi & Sinis 1994, Giguère et al. 1994, Villalba 1995), among other species.

The evolution of the reproductive cycle of *S. marginatus* is, likewise, globally coincident with other references on this species (Rodríguez-MoscOSO et al. 1996, Gaspar 1996, Gaspar & Monteiro 1998, Tirado et al. 2002, Martínez 2002, López et al. 2005) and other Solenidae (Martínez et al. 1997, Casavola et al. 1985, Darriba et al. 2004); with the exception of the well-known expectable

differences in duration and occurrence of the different phases of the cycle due, on the one hand, to feeding, temperature, salinity, photoperiod and, in general, other potentially influent environmental conditions; whereas on the other hand, to probable genetic variations, specially from the Southern population of Terrón Estuary with respect to the northern ones of Eo Estuary and Santander Bay. The aforementioned deviations are also expected

to explain the differences among the three reproductive cycles investigated here.

Spermatogonias and oogonias were analogous to other bivalves (Tranter 1958, Lubet 1959, Darriba et al. 2004). However, some differences with respect to *Ensis arcuatus* were found. Although protogonias have been described in other bivalve species as cells of similar size to oogonias (De Gaulejac et al. 1995), Darriba et al.

Figure 7. Mean total drained weights from: Eo estuary (June to December 1994 and January to May 1995) (triangles); Santander Bay (October to December 1998 and January to September 1999) (squares); Terrón Estuary (January to December 1999) (points).

(2004) described the protogonias of *E. arcuatus* as acidophilic cells bigger than oögonias and reported larger and less basophile oögonias than spermatogonias. Nevertheless in *S. marginatus*, oögonias and spermatogonias showed similar dimensions and degrees of acidophilia.

Distinction between spermatogonias and oögonias in phase I was carried out by the observation of specimens in the transition between the former phase and phase II, in which the subsequent gametogenic stages (i.e., first oocytes and spermatocytes) were clearly observed.

Subphases III A (ripeness), III B (spawning), and III C (restoration) were found simultaneously in only a few animals (Fig. 2, P). In the rest of specimens, two of these three subphases III A to C were always coexisting (Fig. 2M). In consequence, and unlike subphase III D and rest of phases of the reproductive cycle, we did not find razor clams in which the whole follicles were in the same subphase III A to C. Although the decision of classifying the specimens in phase III under one of these three subphases can be based on the state of most of the follicles, subphases III A, III B and III C are not always easy to distinguish in both sexes, as in females: (1) is unusual to find oocytes III A in absence of immature oocytes attached to the follicle wall, and therefore, involved in a simultaneous mechanism of restoration; (2) follicles III A showed frequent intrafollicular spaces, as indicative of a previous spawning. In this way, the loss of the polygonal shape generally observed in the mature oocytes of bivalve mollusks (e.g., Lubet 1959) can be explained as the consequence of a lower intrafollicular compression; (3) follicles III C are also used to show mature oocytes in the lumen. Alternatively, in males: (1) because the production of sperm could be predominant or balanced with production of spermatocytes during subphase III C, it is not clear that in *E. arcuatus* the process of restoration implies, as affirmed by Darriba et al. (2004), a necessary predominance of spermatocytes against spermatozoa in the follicle; (2) in phase II, we observed follicles with a minor proportion of sperm. If we define the mature male follicles as those with predominance of spermatozoa (e.g., Loosanoff, 1942) then the process of maturation of these follicles could have been reached after the emission of at least a portion of the sperm generated during phase II, giving rise to the frequently observed male follicles with broad luminal spaces, which are potentially classifiable under subphase III B. In synthesis, we define subphases III A to C as substages of the reproductive cycle of

frequent coexistence. Therefore, they should be classified more properly at the follicular level than at the individual level, as displayed in Figure 2M, P.

In this study, the gonad of *S. marginatus* was found to be located exclusively inside the foot during all phases of the reproductive cycle. Therefore, our results contradict the findings of Rodríguez-Moscó et al. (1996), authors who affirmed that in *S. marginatus*, the gonad entered the foot during the maturation period.

The function of hemocytes as reserve cells has been investigated by Houtteville (1974) and Medhiboub & Lubet (1988) for the species *Mytilus edulis* and *Ruditapes philippinarum*, who found a set of different transitional stages to reach the final reservoir stage termed vesicular cell. Rodríguez-Moscó et al. (1996) reported a prevalence of glycogen in the muscular tissues and digestive gland of *S. marginatus* and showed that this polysaccharide was poorly represented in the gonad. On the contrary, contents in lipids ranged between 16% and 30%. Remacha-Triviño (2002) found a parallel disorganization and subsequent reorganization of nephridia and gonads in *S. marginatus*, which was hypothesized as an indicative of a probable renal cycle simultaneous to the reproductive cycle. Particularly, the number of hemocytes of the distal limb of the nephridia was demonstrated by Stereology to be significantly increased in phase III. Most of these blood cells were observed to form phagocytic aggregates around the degenerating excretory cells. All these findings were interpreted as a probable mechanism of hemocytic transport of reservoir substances stored in the kidney to the gonad, where hemocytes would tend to remain accumulated as reservoir cells. Darriba et al. (2004) reported a probable feeding activity of the hemocytes of *Ensis arcuatus* by supplying nutrients and carrying out the function of reserve cells in the gonad.

Macroscopic Observation of Gonads

The observation of gonads performed at the macroscopic level permits fast approximations of the reproductive condition and to determine the sex of the specimens in the late stages of the reproductive cycle. Although the macroscopic description of gonads is a general complement to the histological approach in studies dealing with reproduction of bivalves, only a few maturity scales have been pursued in establishing a reliable parallelism at both levels of magnification through all the stages of the reproductive cycle in which this relationship was possible. In this context, the absence of structural perifollicular tissues in *S. marginatus* facilitated the design of a more precise macroscopic maturity scale for the species.

Mean Total Drained Weights

Biometric methods oriented to monitor the reproductive cycle can be classified in: (1) approaches based in one variable (i.e., soft parts weight, shell weight, total weight, soft parts volume, etc.); (2) condition indexes or functions of at least two variables; (3) standardizations derived from the extrapolation of data of (1) and (2) to a concrete value; (4) alternative simple statistical treatments (i.e., descriptive approaches, regressions, etc.); (5) complex statistical or biological treatments (i.e., temporal series or biological models).

Standardizations show the disadvantage of depending on the final value chosen for the extrapolation of data. Thus, results can only be compared in relative terms, unless the same standard value is used for all of the different treatments. In addition, standardiza-

tions would be recommended to be based in unbiased estimators, where the sample mean is likely to be the best and simplest election. Also, approaches (1) to (3) present the inconvenience of being range dependant. Therefore, a rational biometrical comparison should be expected to be derived from sequential range-balanced initial data. Although the previous selection of a fixed range for all the samples compared through time is, in practice, statistically questionable for the cases (1) to (3), as it means to lose the information of the discarded data, a common range can be achieved by statistical simulation (e.g., regression), or it can be chosen in terms of a rational criteria of election.

It is well known that one of the aims of condition indexes is to average the differences caused by size or range by dividing the characteristic of interest (e.g., dry soft parts weight) by a fixed variable, which is expected to remain invariant through time (e.g., dry shell weight). However, no effort is generally made in evaluating these variables separately. If it were so, it could be seen that the trends of some condition indexes widely used [e.g., Higgings' (1938), and Walne's (1970)] and the characteristic of interest can show an inverse relationship with respect to size. This fact can be easily verified by comparing the linear regressions between each one of the variables used in these condition indexes against a common characteristic implying dimension, alternative to the fixed one utilized in the condition index (e.g., for Walne's CI, dry soft parts weight versus shell cavity volume and dry shell weight versus shell cavity volume, since the inverse relationship for Higgings' CI). For instance, if we suppose that equations of the previous regressions were: $Y = X + 1$ and $Z = X/2$, where Y is the dry soft parts weight, X is the shell cavity volume and Z is the dry shell weight, shell cavity volumes of: 2, 4 and 8 cm³ give rise to respective dry soft parts weight of: 3, 5 and 9 g and Walne's CIs of: 3, 2.5 and 2.25. Even for the hypothetical case of parallel slopes (e.g., replacing the second equation $Z = X/2$ by $Z = X - 1$), CIs are: 3, 1.66 and 1.29. Because the previous example demonstrates that the variable of interest can be masked in the CI by the influence of the fixed variable, it seems to be more reliable to apply the approach (1) to monitor the reproductive cycle.

Advantages of the approach applied here based in the sequential mean drained soft parts weights are: (1) A common range for the initial data. Grant and Tyler (1983) affirmed that immature invertebrates should not be included in the analysis of gonad index,

as they will have smaller gonads than mature animals and their gonad weights, oocyte sizes, etc., are unlikely to follow the adult reproductive cycle. In consequence, the lower limit of our interval of shell lengths was restricted to 65 mm as the smaller specimens were not guaranteed to be mature animals. Alternatively, the upper limit of the interval was established in the maximal shell length of the samples. (2) Subsampled data were balanced by simulation and sequential sample means were estimated from a fixed set of values obtained from the arithmetic progression of shell lengths. Therefore, the final data was equally balanced with respect to the size of the specimens. (3) The standardization was unbiased because it was based on sample means. (4) The present biometrical approach involves only one variable (i.e., total drained weight), avoiding CIs. Dry soft parts weight or drained soft parts weight were probably more precise elections. However, we opted to look for the fastest approach, which reflected a reliable evolution of the reproductive cycle.

Accordingly, growth trends and maximums in mean total drained weight comprised between April and June were coincident with Phases III, followed by the falls and growths between June and August of Phases 0. Phases I started when maximums between August and October were reached and Phases II a month later. Finally, minimums between April and March matched the beginning of Phases III.

ACKNOWLEDGMENTS

The authors thank D. Manuel Fernandez Gonzalez, Montserrat Cayado López, the Shellfishermen Cooperatives of Ambojo (Pedreña, Santander) and Terrón Island (Huelva); especially to Pedro Bedia, Felix Ezquerro and Ismael for their help and collaboration during the process of sampling. Angel Gallardo 470, C1405DJR Ciudad de Buenos Aires, Argentina; ³Centro de Estudios Parasitológicos y de Vectores (CONICET-UNLP), 2 N° 584, 1900 La Plata, Buenos Aires, Argentina

ABSTRACT This work describes the parasites and their respective pathologies in the stout razor clam, *Tagelus plebeius* (Lightfoot, 1786) (Psammobiidae) from Argentinean coasts. It represents the first report about a histopathological survey for these species in the Southwestern Atlantic. Specimens of *T. plebeius* were collected at Mar Chiquita coastal lagoon (37°46'S, 57°27'W) ($n = 104$ dissected under stereomicroscope, $n = 28$ histologically sectioned and microscopically examined) and from the mouth of the Quequén Salado River (38°56'S, 60°33'W) ($n = 14$ dissected under stereomicroscope). *Tagelus plebeius* was found housing two ciliate species without apparent host reaction and acting as first intermediate host for two digenetic trematode species of the families Fellodistomidae and Gymnophallidae, by hosting sporocysts (mainly in gonad and digestive gland that results in the replacement of host tissues) and as second intermediate host by housing a gymnophallid metacercaria. Likewise, *T. plebeius* was found parasitized by a larval spirurine nematode encapsulated by hemocytes. The finding of two ciliate species, the gymnophallid cercaria and metacercaria, and the larval nematode represents the first record for the host. The Southwestern Atlantic populations of this clam seem to be devoid of serious pathogens in the study area.

KEY WORDS: *Tagelus plebeius*, pathology, parasites, southwestern Atlantic

INTRODUCTION

The stout razor clam *Tagelus plebeius* (Psammobiidae) inhabits estuarine tidal flats along the American Atlantic coast from Cape Cod, Massachusetts (42°N, USA) (Leal 2002) to the north of Argentinean Patagonia (San Matías Gulf, 41°S) (Scarabino 1977). Despite its wide geographic distribution and its importance as dominant species in intertidal communities of some Southwestern Atlantic estuarine areas, to date a histopathological survey of this clam has not been undertaken. At present, only three parasites have been recorded: a protozoan of the genus *Perkinsus* (Dungan et al. 2002), a digenean larva at sporocyst stage containing trichocercous cercariae (Wardle 1983) and a cestode larva (Holland & Dean 1977). These reports are all from the Northern Hemisphere. Along the Argentinean coast, *T. plebeius* supports a small-scale artisanal fishery. Furthermore, histopathological surveys in commercially exploited bivalves are very scarce in Southwestern Atlantic coast (e.g., Cremonte & Figueras 2004, Cremonte et al. 2005).

The aim of this work is to report the parasites and the histopathologies that they evoke in the stout razor clam, *Tagelus plebeius*, from the Argentinean coast.

MATERIAL AND METHODS

Specimens of *Tagelus plebeius* (Lightfoot, 1786) (Psammobiidae) ($n = 104$) were collected from May 1996 to July 1997 at the intertidal of Mar Chiquita coastal lagoon (37°46'S, 57°27'W), Argentina by excavating the sediment with a shovel. Specimens measured 11–62 mm in maximum shell length (mean = 39). In January 1997, an additional sample of 14 specimens was collected at the mouth of Quequén Salado River (38°56'S, 60°33'W) comprising specimens of 31–68 mm in maximum shell length (mean = 53). Clams were examined for parasites under a stereomicroscope immediately after collection or fixed in 10% formaline to be

examined later. Digenean larvae were studied from whole aceto-carmin stained worms. Nematodes found both free and recovered from their capsules, were stored in 70% ethanol, cleared in lactofenol or alcohol-glicerine and examined under a light microscope. Drawings were made with the aid of a camera lucida. All larval measurements are given in micrometers as mean values followed by the range within parentheses. Ten digenean metacercariae and five nematode larvae were dried using the critical point method, examined with a scanning electron microscope (SEM) (Jeol/SET 100it) and photographed. Prevalence (P) and mean intensity (MI) were calculated according to Bush et al. (1997). In June 2001, the soft parts of 28 clams from Mar Chiquita coastal lagoon, measuring from 26–67 mm of maximum shell length (mean = 55) were fixed in Davidson's solution (Shaw & Battle 1957) for 24 h and stored in 70% ethanol for histopathological survey. Tissue samples were embedded in Paraplast, and oblique transverse sections, approximately 5-mm thick, were taken from each specimen including mantle, gills, gonad, digestive gland, nephridia and foot. They were stained with haematoxylin and eosin. Histological sections were examined by light microscope under $\times 400$ magnification for presence of parasites and pathological alterations.

To estimate the total number of metacercariae present, the cluster of larvae was detached, divided in four equal parts, the larvae present in one quarter counted and multiplied by four. The intensity of color and the calcareous alterations of the inner surface of shells were ranked in four categories as follows: 0 = no alteration, 1 = only dorsal area of shell slightly colored, 2 = dorsal area of shell heavily colored and extended to pallial sinus and 3 = almost the entire inner shell surface heavily colored with calcareous alterations present. The maximum shell length, the number of metacercariae and the intensity of shell alterations (using the 4 above referred categories) were correlated by a Spearman-rank test (Moraes & Pino 1987).

Histological sections of parasitized clams were deposited at the Helminthological and Protozoological Collections, Museo de La

Plata (MLP No. 5624, 5624/1, 5624/2 and MLP 023, 023/1, and 023/2), La Plata, Argentina; some valves of the examined clams were also deposited at the Malacological Collection, Museo de La Plata (MLP No. 5696).

RESULTS

A total of six parasitic or commensal taxa were found in the clam samples examined; two of them were ciliate protozoans and the other four, metazoan parasites. Prevalences and mean intensities of infection found at both study sites are given in Table 1.

All measurements in this section will be assumed to indicate microns.

Ciliate sp. 1

This protozoan was found in clams examined alive and from histological sections, mostly parasitizing the base of the gills in low intensities of infection (Table 1, Fig. 1 [2]).

Ciliate sp. 2

This ciliate, which is similar to a *Trichodina* species, was also found in clams examined both alive and from histological sections parasitizing the gills in low intensities (Table 1).

Fellodistomid Cercaria sp.

General Morphology

According to Cable (1956), a fellodistomid cercariae can be identified by the following characteristics: Distome, pharyngeate larva, tegument spinose or smooth, eyespots present or absent, stylet lacking, excretory vesicle thin-walled, and a long and slender trichocercous tail, developing in marine bivalves.

Sporocyst [measurements based on 10 mounted specimens]

Elongated, thick-walled sac without constrictions, 2,520 (1,750–3,051) in length by 310 (260–370) in maximum wide, each containing 10–21 (mean: 14) trichocercous cercariae at different developmental stages (Fig. 1 [3, 4]).

Cercaria [not released, measurements based on the 10 largest mounted specimens]

Body oval to pyriform, 343 (328–362) long by 154 (123–175) wide. Tegument spinose. Oral sucker subterminal. 65 (58–71) long by 67 (62–73) wide. Forebody (distance from anterior end of body to anterior edge of ventral sucker) 127 (120–135). Ventral sucker 52 (47–56) long by 51 (46–54) wide. Sucker ratio (ventral sucker length/oral sucker length): 1: 0.80 (0.79–0.81). Prepharynx absent.

Pharynx ovoid, 43 (39–52) long by 33 (31–37) wide. Esophagus 23 (17–30) long. Caeca bifurcating just anteriorly to ventral sucker, 151 (140–160) long by 18 (16–21) wide. Parenchyma full of cystogenous cells. Excretory vesicle V-shaped, arms reaching acetabular level; caudal excretory tubule conspicuous, opening at end of tail in two pores. Primordial testes opposite, located at the level of the caecal end. Tail 484 (452–520) long by 47 (43–51) wide, with about 25 finlet-like structures on each side with 15 (9–22) setae joined by a membrane (Fig. 1 [5]).

Site of Infection

Mainly in gonad, also in digestive gland.

Histopathology

Sporocysts were replacing host tissues (Fig. 1 [3]).

Gymnophallid cercaria sp.

General Morphology

According to Bartoli (1974), a gymnophallid cercaria can be identified by the following characteristics: Distome, pharyngeate larva, tegument spinose, eyespots absent, stylet lacking, excretory vesicle thin-walled V or Y shaped, furcated tail, developing in marine bivalves.

Sporocyst [measurements based on 10 mounted specimens]

Elongated, thin-walled sac without constrictions, 750 (470–1101) long by 250 (160–331) in maximum wide, each containing 50–55 (mean: 50) furcocercariae at different developmental stages (Fig. 1 [6a]).

Cercaria [not released, measurements based on the 10 largest mounted specimens]

Body minute, transversely spinose, 136 (126–151) long by 61 (52–67) wide at ventral sucker level. Oral sucker opening subterminally, 35 (30–41) long by 31 (29–36) wide. Ventral sucker located in hindbody, 25 (23–28) in diameter. Sucker ratio (ventral sucker length/oral sucker length): 1:1.4 (0.68–0.77). Pharynx ovoid, 20 (16–23) long by 15 (12–17) wide. Esophagus 15 (13–16) length. Caeca short, reaching acetabular level. Excretory vesicle V-shaped filled with excretory granules, arms reaching pharynx level, opening on the inner side of each furca end. Tail stem 45 (41–51) in length, furcae 55 (50–65) in length (Fig. 1 [6b]).

Sporocyst of Fellodistomidae (Digenea), scale bar = 200 µm. 5a. Cercaria of Fellodistomidae, scale bar = 200 µm. b. Detail of a set of the trichocercous furcae, scale bar = 30 µm. 6a. Sporocyst of Gymnophallidae (Digenea), scale bar = 200 µm. 6b. Cercaria of the family Gymnophallidae, scale bar = 50 µm.

Site of Infection

Mainly in gonad, also in digestive gland.

Histopathology

Sporocysts were replacing host tissues.

Gymnophallid metacercaria sp.

General Morphology

According to Bartoli (1974), a gymnophallid metacercariae can be identified by the following characteristics: small or minute worms, tegument spinose, oral sucker larger than ventral sucker with or without lateral projections, ventral sucker equatorial to postequatorial, excretory vesicle V or Y shaped, with long lateral arms extending to pharyngeal level and filled with excretory granules. Reproductive organs in an advanced stage of development (testes opposite to diagonal, ovary pre or post testicular).

Metacercaria [measurements based on 10 largest mounted specimens]

Body small, oval to pyriform, 329 (284–374) long by 167 (110–230) wide at ventral sucker level. Body rounded when enveloped by host tissues. Spines arranged transversely over all body length. Oral sucker subterminal, 70 (46–90) long by 75 (27–90) wide, with two conspicuous lateral projections. Twelve papillae located around oral sucker opening. At least 5 pairs of cephalic glands opening dorsally to oral sucker. Ventral sucker post equatorial, 35 (30–41) in diameter, with 6 papillae. Sucker ratio (ventral sucker length/oral sucker length): 1:0.46 (0.50–0.65). Pharynx ovoid, 34 (29–38) long by 29 (23–41) wide. Esophagus 19 (10–40) in length. Caeca 84 (63–98) long by 54 (37–88) wide, reaching acetabular level. Testes ovoid to rounded, located postero-lateral to ventral sucker, symmetrically to obliquely disposed. Testis posterior to ovary, 49 (37–60) long by 41 (32–58) wide; testis opposite to ovary 46 (28–62) long by 42 (34–47) wide. Ovary rounded, pretesticular 30 (28–32) in diameter. Genital pore wide, oval, located somewhat apart and anteriorly to ventral sucker. Genital atrium oval and shallow. Vitellaria formed by two compact lobes, located at sides of ventral sucker. Excretory vesicle V-shaped, with diverticulated arms reaching oral sucker and filled with excretory granules (Fig. 2 [7–10]).

Site of Infection

Metacercariae lay forming a compact and easily detachable cluster (see Fig. 3 [13] later) just below the dorsal shell margin, immediately below hinge and above the rectum (Fig. 2 [11]). In heavy infections metacercariae were also found in the extrapallial space adjacent to the anterior end of the pallial sinus (Fig. 2 [11] Fig. 3 [13]).

Histopathology

Macroscopically, metacercariae appear crowded, forming an orange-colored cluster enveloped by host tissues (Fig. 3 [13]). In heavy infections, a brownish-orange pigmentation is also present on the inner shell surface at the sites where metacercariae are located (Fig. 3 [12]) (i.e., below hinge) and also along the pallial sinus. In histological sections, each metacercaria appear surrounded by a hyaline, non cellular envelope, which is formed by several concentric layers (Fig. 3 [14]). This envelope has a jelly-like appearance under the stereomicroscope (Fig. 3 [13]). Metacercariae and their envelope are surrounded, individually or in groups, by a sac formed by one-cell-thick cubic or somewhat

flattened epithelium (Fig. 3 [14]), which results from the invagination of the outer mantle epithelium at the isthmus region. Cumuli of orange pigment were observed as amorphous aggregates, between the epithelial layer and the hyaline envelope of each metacercaria (Fig. 3 [14]). In some clams, abnormal calcifications in the form of loose calcium concretions or growth disruptions on the inner shell surface were present, which were from slightly to strongly colored (Fig. 3 [12]). Small calcareous concretions like pearls or amorphous calcium carbonate were also found within sacs, near dead metacercariae (Fig. 3 [12–14]).

Relationship Between Shell Length, Shell Alteration and Intensity of Infection by *Gymnophallid metacercariae*

Spearman-rank correlation test was statistically significant in all cases ($n = 104$; $P < 0.001$), $r_s = 0.85$ obtained when plotting maximum shell length and intensity of infection by metacercariae; $r_s = 0.45$ obtained when plotting maximum shell length and shell alteration; $r_s = 0.45$ obtained when plotting intensity of infection by metacercariae and shell alteration.

Spirurina larval nematode

General Morphology

According to Chaubaud (1975), a nematode with the following characteristics can be included into the Order Spirurida Chaubaud, 1975. Suborder Spirurina Chaubaud, 1974: anterior extremity bilaterally symmetrical, pseudolabia well developed, esophagus divided into an anterior muscular portion and a posterior, longer and glandular portion.

Description [measurements based on 20 specimens]

Stout small nematode with cuticle finely and transversely striated and pseudolabia well developed. The lateral groove starts in the anterior part and ends near fasmids. Two cephalic papillae are at each side, and amphids large with Deirids absent. Body unarmed, 1,238 (805–1,610) long by 47 (32–68) wide. Esophagus elongate, clavate, 278 (102–410) long; divided into anterior muscular part, 116 (88–149) long, and posterior glandular part, 177 (109–272) long. Nerve ring slightly anterior to the junction of both parts of esophagus, distant 106 (91–123) from anterior end. Excretory pore 185 (129–223) from anterior end. Genital primordia observed in some specimens as one cell located in the middle of body length. Three rectal cells (one dorsal and two ventral). Tail conical, 96 (81–120) long, ending in a sharp cuticular spike (Fig. 4 [15–19]).

Site of Infection

Muscular wall of visceral mass (48%), labial palps (28%), siphon retractor muscles (8%), adductor muscles (8%), radial muscles of the mantle border (4%), mantle (4%) (Fig. 5 [20–23]).

Histopathology

Larvae are found free or individually surrounded by a capsule. At the stereomicroscope, the capsule appears as a brownish spot that measures 1–3 mm in diameter; larva inside is alive and able to move. The degree of tissue reaction elicited by the presence of this parasite varies from no reaction to the formation of a thick capsule (Fig. 5 [20–23]). Histological sections show that the capsule is formed by a dense aggregation of hemocytes (Fig. 5 [22, 23]). In some cases, bundles of fibers of the muscle affected are seques-

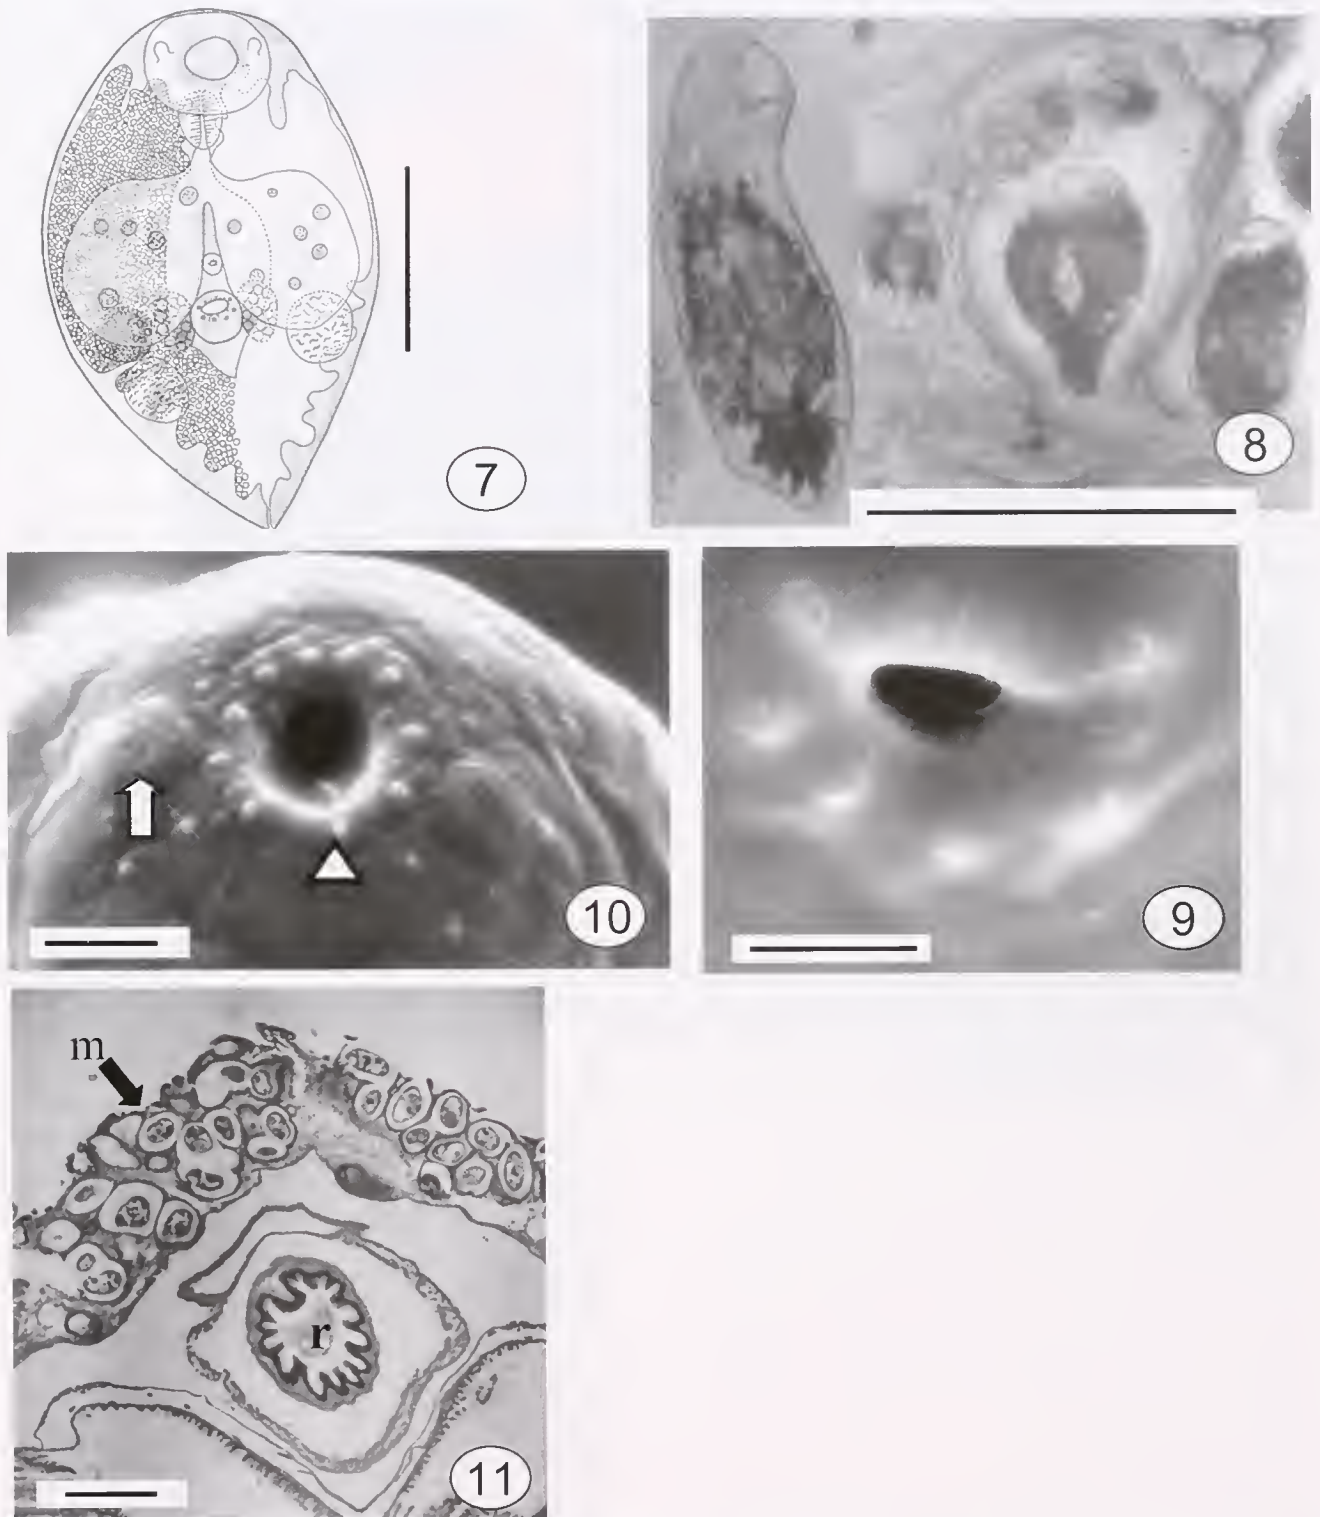

Figure 2. Parasites of *Tagelus plebeius* from Southwest Atlantic coast. 7. Metacercariae of Gymnophallidae, scale bar = 100 μ m. 8. Live specimens of metacercaria of the family Gymnophallidae, scale bar = 300 μ m. 9. Detail of oral sucker at SEM, note the two lateral projections slightly retracted (arrow) and papillae (arrow head), scale bar = 10 μ m. 10. Detail of ventral sucker at SEM, note the six papillae, scale bar = 10 μ m. 11. Histological section of dorsal part where gymnophallid metacercariae are located scale bar = 200 μ m. References: m = metacercaria, r = rectum.

tered to form part of the outer wall of the capsule (Fig. 5 [23]). In other cases, the reaction complex only causes the splitting of the adjacent muscle fibers; however, the later do not form part of the capsule.

DISCUSSION

The present report is the first parasitological survey of the stout razor clam *Tagelus plebeius* from the Southwestern Atlantic

Figure 3. Shell alterations in *Tagelus plebeius* caused by gymnophallid metacercariae. 12a. Left valve strongly colored in a specimen with high parasitic infection by gymnophallid metacercariae; 12b. Left valve slightly colored in a specimen with light parasitic infection of gymnophallid metacercaria, scale bar = 2 cm. 13. Metacercaria crowd removed from a bivalve specimen, scale bar 1000 μ m. 14. Histological section of *Tagelus plebeius* showing the pigment accumulated inside the sacs, scale bar = 200 μ m. References : m = metacercaria; a = noncellular matrix; p = orange pigment; e = epithelium.

Ocean. The finding of two ciliate species, the gymnophallid cercaria and metacercaria, and the larval nematode represent first records for the host. The only digenean previously recorded in *T. plebeius* is a fellodistomid cercaria (Wardle, 1983). The larval cestode (Holland & Dean 1977) and the protozoa species of *Perkinsus* (Dungan et al. 2002), all reported from the Northwestern Atlantic coast were not found in this study. From biogeography point of view, this result is in accordance with that hypothesized for many adult parasites: most parasite species have restricted, continental, geographical distributions, even though their hosts have wider, intercontinental, distributions (Carney & Dick 2000).

Tagelus plebeius was found acting as first intermediate host for two digenetic trematode species of the families Fellodistomidae and Gymnophallidae, hosting the sporocyst stage. Most trematode species parasitize gastropods. Only a few families infect bivalves, and as were found in this study, low prevalences were the rule (Lauckner 1983). In our study, sporocysts of both families were found replacing host tissues without host reaction. They do not become encapsulated when they are found in their natural intramolluscan habitats because both are well adapted with each other (Cheng & Rifkin 1970).

According to Bray (1988), nonoculate cercariae carrying long trichocercous tails without furcae, with fin-like setae joined by a membrane and spinose tegument belong to the subfamily Baccigerinae Yamaguti, 1958. Thus, the fellodistomid cercaria observed in the present study likely belongs to the subfamily Baccigerinae. The life cycle of Baccigerinae involves a heterodont bivalve, which acts as first intermediate host, some representative of gelatinous plankton or a crustacean usually act as second intermediate hosts and fishes are the definitive host (Bray 1988).

As regard the finding of cercaria of the family Gymnophallidae, its identification below family or subfamily level is not possible

because cercariae of different species in this family are almost indistinguishable (Lauckner 1983). Because most gymnophallid life cycles have a swimming cercaria that enter in a second intermediate host that is the same species as the first one, it seems probable that gymnophallid cercaria found belongs to the same species that the metacercaria hosted by *T. plebeius* (Cremonte 2004). It would be necessary to perform experimental infections to confirm this assumption and to obtain the adult form to identify it at genus and species level. High prevalences and intensities of gymnophallid metacercariae (Table 1) could be explained by the hydrodynamic of the studied environment. The quiet circulation of water masses facilitates the transmission of cercaria (Bartoli 1984). The oystercatcher, *Haematopus palliatus* (Aves: Haematopodidae) seems to be the definitive host, because it was reported to feed mainly on *T. plebeius* along this environment (Bachmann 1995).

The only gymnophallids reported from South American mollusks are *Lacumovermis* sp. from *Patinigera* spp. (Gastropoda: Patellidae) (Martorelli & Morriconi 1998), *Bartolius* sp. from *Gaimardia trapesina* (Bivalvia: Gaimardiidae) (Ituarte et al. 2001) (both from Magellan Strait and Beagle Channel) and *Bartolius pierrei* from *Darina solenoides* (Bivalvia: Mactridae) from Patagonian coast (Cremonte 2001).

Regarding the pathology caused by metacercariae of the family Gymnophallidae, it is variable and depends on the parasite and the host species involved (e.g., deposition of additional shell material in the form of calcareous concretions, blisters and crests, ridges, or igloo-like structures on the inner surface of the valves, pearls, shell erosions like pits, depletion of host body reserves, alterations of host behavior and general debilitation and morbidity) (Lauckner 1983, Ituarte et al. 2001, Cremonte & Ituarte 2003, Ituarte et al. 2005). In the present case, the host reaction observed in *T. plebeius* is very similar to that reported in *D. solenoides* infected by *B.*

Figure 4. Larval nematode of the subfamily Spirurinae. 15a. posterior extremity; 15b. anterior extremity, scale bar = 50 μm (16–19). SEM photographs of the larval spirurine nematode in *Tagelus plebeius* from Argentina. 16. Whole coiled worm, scale bar = 100 μm . 17. Initial formation of capsule by hemocytes (h) in connective tissue of mantle, scale bar = 50 μ m. 23. Advanced stage of a capsule formed by hemocytes in tegument musculature (arrow), scale bar = 100 μ m. References: n = nematode; m = mantle; h = hemocytes.

pierrei (Cremonte & Ituarte 2003). The main difference observed in *T. plebeius* is the presence of a brownish-orange colored pigment within sacs containing larvae, particularly in older bivalve hosts, in concordance with correlations among shell length, shell alteration and intensity of infection observed. A similar but yellowish conchiolin material was reported in *Tellina* spp. (Bivalvia: Tellinidae) by Giard (1897) and brownish material by Bartoli (1974) in *Tapes aureus* (Bivalvia: Veneridae) infected by gymnophallid metacercariae.

Metacercariae of Gymnophallidae are known to be able to prevent nacreization around them, allowing most larvae to remain alive inside their envelope until reaching a suitable definitive host. This peculiarity of the gymnophallids encapsulation was discussed by Ituarte et al. (2001), Cremonte & Ituarte (2003) and Ituarte et al. (2005). However, in advanced stages of parasitism (i.e., in older infections) it seems that several metacercariae die, and just after this, the deposition of calcium to form blisters seems to be possible. In *T. plebeius*, calcium concretions in the form of blisters or loose pearls were only seen in older clam specimens, and seem to affect a reduced number of adult bivalves. Lomovasky et al. (2005) reported this phenomenon in only the 5.9% of the 620 specimens of *T. plebeius* studied.

Marine bivalves, as a group, are rather uncommon hosts for

nematodes. However, ascaridoids and gnathostomids have been reported several times from representatives of commercially exploited bivalve species (Lauckner 1983). The nematode taxa more frequently reported from marine bivalves are *Sulcascaris sulcata* (Ascaridoidea: Anisakidae) and *Echinocephalus* spp. (Gnathostomoidea: Gnathostomidae); their adults occur in fishes, which prey on clams (Sindermann 1990). The nematode larva described in this study clearly does not correspond to an ascaridoid, because it has pseudolabia and an esophagus divided into glandular and muscular portions (Anderson et al. 1974). Moreover, the larva described here is not a gnathostomid because it has not trilobed pseudolabia and lacks the anterior extremity swollen into bulb (Anderson et al. 1974). Thus, the present record represents a new group of nematode using marine bivalves, *T. plebeius* in this case, as intermediate or paratenic hosts.

High values of prevalence and mean intensity of infection found in this study (Table 1) indicate these are not cases of an accidental infection. This represents the first record of a nematode larva parasitizing a bivalve in the Southwestern Atlantic Ocean. Because all nematodes found in marine bivalves are larvae, they are extremely difficult to identify (i.e., lack the diagnostic characters that are carried by the adult stage); thus, the importance of nematodes as parasites of this group have been sadly neglected

(Cheng 1978). The nematode larva described in this survey is not specific regarding its site of infection, being located mainly in muscles but also in other organs such as labial palps. Sites of infection of larval nematodes in other bivalves also showed to be highly variable: *Echinocephalus uncinatus* Molin, 1858 was found in the adductor muscle of pearl oyster *Margaritifera vulgaris*, *E. pseudouncinatus*, Millemann, 1951 in the foot of pink abalone *Haliotis corrugata* (Millemann 1963) and *E. crassostreai* Cheng 1975 in the gonoducts of Japanese oyster *Crassostrea gigas* with a reaction of the tunic elements that are surrounding the gonoduct (Cheng 1975).

The pathogenicity of larval nematodes in marine bivalves varies from nonreaction to a strong tissue response (Ko et al. 1975). Different degrees of host reaction observed in the present work would correspond to the time of infection. The capsule formed by a dense aggregation of hemocytes such as observed in *T. plebeius*,

is known as hemocytosis according to Cheng & Rifkin (1970). Despite the large number of capsules studied, fibrous-appearing nodules as it was described by Harris (1975) for the case of *Angiostrongylus cantonensis* (Metastrongylidae) parasitizing a gastropod, were not observed. Harris (1975) noted some variability in the extent of response even within the same snail host. In that case, the granuloma loses the appearance of a loose aggregation of basophilic cells and becomes more fibrous and eosinophilic, similar to the capsule reported for the cestode *Echineibotrium* sp. by Cheng (1978).

COMPARISON OF ASSIMILATION EFFICIENCY ON DIETS OF NINE PHYTOPLANKTON SPECIES OF THE GREENSHELL MUSSEL *PERNA CANALICULUS*

JEFFREY S. REN,* ALEX H. ROSS AND BARBARA J. HAYDEN

National Institute of Water and Atmospheric Research, PO Box 8602, Christchurch, New Zealand

ABSTRACT The greenshell mussel *Perna canaliculus* is the most important species in aquaculture in New Zealand. Mussel energetics and growth rates are subject to the natural variability in phytoplankton biomass and species composition and thus understanding the influence of food type on assimilation efficiency is fundamental to the prediction of mussel production and planning farm management. In this study pulse-chase feeding techniques were used to assess the effect of diet on assimilation efficiencies for nine phytoplankton species including three diatoms *Chaetoceros calcitrans*, *Skeletonema costatum* and *Thalassiosira* sp., and three flagellates *Eutreptiella* sp., *Pyramimonas* sp. and *Isochrysis galbana*, and three dinoflagellates *Akashiwo sanguineum*, *Alexandrium minutum* and *Gymnodinium catenatum*. Assimilation efficiency varied with algal species, but it was significantly higher when mussels were fed dinoflagellates (84.5%) compared with diatoms (61.7%) and flagellates (77.9%). Assimilation efficiency of dinoflagellates and flagellates increased with gut passage time, whereas with a diatom diet, a negative correlation was evident. This finding has implications in understanding and predicting growth rates of mussels (and hence commercial yield) in tandem with natural variability in phytoplankton species composition.

KEY WORDS: mussel, *Perna canaliculus*, phytoplankton, assimilation efficiency, gut passage time

INTRODUCTION

The feeding responses of bivalves to variations in the quantity and quality of seston have been extensively studied (see reviews by Winter 1978 and Jørgensen 1996). Results of these studies have shown the ability of bivalves to preferentially ingest organic particles from the filtered matter and selectively reject the inorganic particles. Many of these feeding experiments have been conducted on blue mussels (e.g., Bayne et al. 1989, Bayne et al. 1993, Navarro et al. 1992), oysters (e.g., Newell & Jordan 1983, Barillé et al. 1997, Ren et al. 2000), scallops (e.g., Cranford et al. 1998), clams (e.g., Hartwell et al. 1991), and cockles (Iglesias et al. 1992 & Iglesias et al. 1996). Few studies used *P. canaliculus*, the greenshell mussel (Hawkins et al. 1999). In these studies, diets of either natural seston or natural food with addition of algae were used to understand the effects of food quantity and quality on feeding dynamics. Seston-phytoplankton mixed diets generate a blended assimilation that reflects a diversity of particle sources and quality. To our knowledge however, relatively little attention has been paid to the preferential ingestion among phytoplankton species (e.g., Romberger & Epifanio 1981, Shumway et al. 1985).

Considerable intra-annual variations in growth rates and conditions of farmed shellfishes have been observed in Marlborough Sounds, New Zealand (e.g., Ross et al. 1997, Ross & Image 2001). This reflects the complex ecophysiological response of mussels to the equal complexity of interactions among environmental variables. High phytoplankton biomass usually results in fast growth and increase in condition of mussels (Ren & Ross 2005). Chlorophyll-*a* pigment concentration is often used to estimate phytoplankton biomass in field monitoring and, therefore, can be an indicator of environmental conditions that influence mussel growth. Over the last few years, the chlorophyll-*a* concentration in Marlborough Sounds has generally decreased and there have been concurrent decreases in both the condition and growth rate of the mussels (e.g., Ross et al. 1997, Ross & Image 2001). Although these trends appear to be broadly related, there have been occa-

sions when mussel growth has been poor even though surrounding chlorophyll-*a* levels have been moderate (Ren & Ross 2002). These discrepancies may relate to the differential consumption of phytoplankton species or groups. During the same period, the composition and abundance of the phytoplankton was characterized by strong intra and interannual variations in the extensive mussel farming area of Marlborough Sounds. This variation may even be pronounced during seasons of algal blooms when one single species usually dominates the phytoplankton biomass (Mackenzie et al. 1986, Ogilvie 2000). This raises the question on whether mussels can assimilate some algal species with greater efficiency than others and hereby show good growth even when chlorophyll-*a* as an indicator of total phytoplankton biomass is low. Selective ingestion on different algal species has been observed in other mussel species (e.g., Kreeger et al. 1996, Wang & Fisher 1996). The mussel *Mytilus galloprovincialis* preferentially selects dinoflagellates rather than diatoms and digestion rate of the dinoflagellates may also vary among species (Sidari et al. 1998). Although a few studies on feeding behavior of *P. canaliculus* have been done (Hawkins et al. 1999), very little is known of the selective assimilation in this species. To assess energy flows through a mussel-farmed ecosystem it is essential to quantify the efficiency with which the mussels assimilate the phytoplankton species and groups that inhabit the Marlborough Sounds.

Assimilation efficiency is usually estimated from direct measurements based on the ash ratio between the food source and feces as developed by Conover (1966). This ratio is embodied in the mass balance equation that assesses scope for growth, which is based on measured difference between energy gains from feeding and energy loss for respiration and excretion (Baynes & Newell 1983). However, the relationship between estimated growth from mass balance models and actual growth has not been convincingly described in bivalves (e.g., Riisgård & Randøl 1981). By comparing estimated and actual growth of mussels, the authors found that estimation of assimilation efficiency gave unreliable results. Although uncertainty in modeling techniques may not be ruled out (see van Haren & Kooijman 1993), limitations of the methods used in physiological measurements may, to some extent, have contributed to the error of estimated assimilation efficiency. As discussed by Conover (1966), when the diet consists of a low ratio of ash to

*Corresponding author. E-mail: j.ren@niwa.co.nz

organic content such as phytoplankton, a significant proportion of ash can be absorbed. This would result in uncertainties in estimated assimilation under such a condition. This method also requires a large amount of material and is susceptible to weighing errors even when using a microbalance (Navarro & Thompson 1994). In shellfish farming ecosystems such as Marlborough Sounds of New Zealand, the contribution of phytoplankton biomass to total organic particulate matter is usually very low in terms of dry weight, but it is the main energy sources for bivalve growth. Small errors in measurements can potentially result in considerable larger errors in estimation of energy budgets (Ren & Ross 2005). Therefore, accuracy in estimates of the bioenergetic parameter is critical for the study of mussel energetics.

In this study, we used a radiotracer technique to investigate how mussels respond to different food diets. Assimilation efficiencies were measured in *P. canaliculus* using nine phytoplankton species found in a mussel-farming ecosystem in Marlborough Sounds, New Zealand. This study is aimed at providing information for parameterizations of energetic and carrying capacity models currently being developed (Ren & Ross 2005).

MATERIALS AND METHODS

Mussels

Three hundred mussels (*P. canaliculus*, ~70 cm shell length) were collected on one occasion from a farming site in Marlborough Sounds, New Zealand. They were transported immediately to and kept on ropes in Magazine Bay near Christchurch for use in the experiments. For the feeding trial, 54 mussels were transferred to the NIWA laboratory in Christchurch and acclimatized in a recirculating aerated flow-through seawater system for 72 h prior to feeding experiments. During the acclimatization period, mussels were fed with a diet of mixed algae consisting of nine experimental algae with equal numbers of each species. Approximately 1×10^9 cells of the algae were added each day per mussel to ensure that physiological activities of the animals were not affected because of starvation. Seawater was collected directly from Christchurch coast and stored in three holding tanks. Because the seawater was kept in the dark and aerated in the laboratory for over 6 wks before experiments, there were no living algae in the water at the time of use. Seston, particulate organic matter and chlorophyll-*a* concentrations were 2.15 mg L^{-1} , 0.49 mg L^{-1} and $\sim 0 \text{ } \mu\text{g L}^{-1}$ respectively. Temperature was constant at $\sim 16^\circ\text{C}$. The seawater was recirculated and monitored once a day for ammonia concentration using ammonia test kits. Throughout all experiments, the ammonia concentration never exceeded 1 ppm.

Experimental Diets

An important aspect of this study was to measure assimilation efficiency that can be incorporated into energetic and carrying capacity models applied in mussel farming ecosystems. It is therefore important that these measurements be conducted on diets reflecting natural conditions. In mussel farming sites of the Marlborough Sounds, there is little variation in POM, whereas there is a considerable inter and intra annual variation in phytoplankton species composition. Phytoplankton contributes very little to POM in terms of dry weight (<10%, e.g., Ren 2001), but it is the major food sources for bivalve growth in terms of available suspended particulates (e.g., James & Ross 1996, Ogilvie 2000). Therefore, to

be representative of the natural condition, experimental diets were based on ^{14}C labeled algae.

Nine phytoplankton species, *Chaetoceros calcitrans*, *Skeletonema costatum*, *Thalassiosira* sp., *Akashiwo sanguineum*, *Alexandrium minutum*, *Gymnodinium catenatum*, *Eutryptiella* sp., *Isochrysis galbana*, *Pyramimonas* sp., belonged to diatom, flagellate and dinoflagellate, were cultured at the NIWA aquaculture laboratory at Mahanga Bay. The algae were enumerated by particle counter (Model ZM and tube with $100\text{-}\mu\text{m}$ orifice diameter). The algae were spiked with ^{14}C ($100 \text{ } \mu\text{Ci mL}^{-1}$) by exposing the algae to the radiotracers for 3 d and kept in 12:12 light-dark photoperiod at 17°C . To calculate ^{14}C -uptake after 3 d exposure, 2 mL replicate samples were each filtered through a 25 mm diameter GF/F filters ($0.7\text{-}\mu\text{m}$ pore, Whatman). These filters were then added to 1 mL 5% HCL and held for over 6 h for liquid scintillation cocktail for analysis (LKB Wallac 1217 Rackbeta) of ^{14}C -activity. Before feeding to mussels, the algal cells were separated from their culture medium by centrifugation (1000 g, 10 min) to remove dissolved ^{14}C . The algal pellets were rinsed with $0.7\text{-}\mu\text{m}$ filtered seawater. This process was repeated three-times to remove surface attached chemicals. The cells were resuspended in 100 mL seawater and enumerated for the feeding experiments as described below.

Experiments with Mussels

Radiolabeled algae were transferred into a 20-L container and mixed with 15 L seawater (no living algae). Nine experimental trials were conducted simultaneously and experimental diets were prepared by adding ^{14}C labeled algae into seawater. Each experimental trial was identical except that mussels were fed on different ^{14}C labeled algal species. Six replicate individual mussels were then placed in the container containing the mixture of seawater and radiolabeled algae ($\sim 1 \times 10^5 \text{ cells mL}^{-1}$) for 30 min. The duration of the feeding was assumed sufficient to allow mussels to ingest a substantial amount of the labeled algae but not defecate, because the experimental duration was less than gut transition time of 80 min (Hawkins et al. 1999). The solution was stirred and aerated to homogenize algae during the course of the feeding trial. Pseudofeces production was not observed; this was probably caused by particulate concentrations of the diets being lower than the threshold for pseudofeces production. Feces were collected at the end of the feeding trial, but ^{14}C activity in these were negligible.

After feeding with radiolabeled algae, the mussels were rinsed with seawater and transferred into a flow-through system to "chase" the unassimilated material through the gut. The mussels were fed with unlabeled mixed algal diet the same as prior to the experiment. In a separate pilot trial, gut evacuation time of the mussel varied with algal species, but most of ingested diets were evacuated within 30 h. In this experiment, mussels were allowed to evacuate their guts for 3 d. This was also based on evidence that *Mytilus edulis* completes its digestion and assimilation of food within 3 d (see Wang et al. 1995). Feces produced by individual mussels were collected with a wide-pore pipette to monitor gut passage of the radioactive algae every 1–3 h for the first 10 h and every 4–20 h thereafter. Feces were filtered onto 25 mm diameter GF/F filters ($0.7 \text{ } \mu\text{m}$ pore, Whatman) and individually placed into 20 mL scintillation vials until analysis.

After a 3 d pulse-chase feeding experiment, ingested ^{14}C algae were to have been assimilated and incorporated in the mussel flesh, which was then dissected from the shell, added to a tared aluminum weighing pan, freeze-dried and then reweighed to determine

total dry flesh weight of each mussel. Dried flesh of individual mussels was then ground with a mortar and pestle and three replicates of ~200 mg were placed into 20 mL scintillation vials for counts of incorporated ^{14}C . The powdered sample was homogenized in 1 mL of distilled water and left overnight at room temperature. The next day, 1 mL of tissue solubilizer was added into each vial, which were then incubated in a water bath at 95 °C for 5 h before 10 mL "HiSafe"-III liquid scintillation cocktail was added. The homogenate solution was thoroughly mixed, left overnight and counted using a liquid scintillation counter (LSC) to determine ^{14}C incorporation. Resulting counts per minute were converted to decays per minute using a quench curve and the external standard technique with correction for background radioactivity.

For the analysis of ^{14}C in feces, 1 mL of 5% HCL was added into each vial containing feces and left overnight to breakdown any possible undigested algal cells. Ten milliliters "HiSafe"-III liquid scintillation cocktail was added into each vial and ^{14}C was counted using LSC as above. The total ^{14}C activity was summarized from all collections of feces during the 3 d pulse-chase feeding period.

Statistical Analysis

Assimilation efficiency (AE) was defined as the proportion of ingested ^{14}C retained after completion of digestion and gut evacuation of ^{14}C within 3 d, as

$$AE = {}^{14}\text{C}_{\text{flesh}} / ({}^{14}\text{C}_{\text{flesh}} + {}^{14}\text{C}_{\text{feces}})$$

where ${}^{14}\text{C}_{\text{flesh}}$ is ^{14}C incorporated in the flesh and ${}^{14}\text{C}_{\text{feces}}$ is ^{14}C egested in the feces during the 72 h pulse-chase feeding period. This method is based on the assumption that respired and excreted ^{14}C are negligible (e.g., Wang & Fisher 1996, Charles & Newell 1997). For example, Charles & Newell (1997) showed that respired ^{14}C contributed as little as 0.4% to the total ingested ^{14}C in the mussel *Genkensis demissa*.

Following Wang & Fisher (1996), gut passage time (GPT) is defined as the time at which 90% of the accumulated ^{14}C in the feces is recovered, assuming 100% recovery at 3 d pulse-chase feeding period.

Multiple comparison tests on data were used to detect significant differences of assimilation efficiency between food algal types (95% confidence level). Linear regression model was used to analyze correlation between AE and GPT. All analyses were done using S-PLUS. (Insightful Corp.)

RESULTS

Defecation and Gut Passage Time

No pseudofeces were detected during the experiments indicating that the concentration of total particulate matter was below the threshold for pseudofeces production. The defecation of nine-tested phytoplankton species in mussels after radioactive pulse feeding is shown in Figure 1. In general, the unassimilated portion of ingested radioactive phytoplankton showed a rapid loss through feces within the first few hours. However, the defecation rate varied considerably among phytoplankton species, being the fastest on a diet of *Alexandrium minutum*, *Chaetoceros calcitrans* and *Skeletonema costatum*, whereas *Thalassiosira* sp. and *Gymnodinium catenatum* were egested with slow rates. This defecation pattern can be shown more clearly using gut passage time (GPT) because this showed a large variation between food types, ranging

Figure 1. Time-series accumulated percentage of DPM in the feces after a pulse ingestion of radiolabeled phytoplankton by the greenshell mussel *Perna canaliculus*. Symbols: \blacklozenge = *Chaetoceros calcitrans*, \circ = *Skeletonema costatum*, \blacktriangle = *Thalassiosira* sp., \triangle = *Akashiwo sanguineum*, \blacksquare = *Alexandrium minutum*, \bullet = *Gymnodinium catenatum*, \square = *Eutreptiella* sp., \diamond = *Isochrysis galbana*, * = *Pyramimonas* sp. Confidence intervals have been omitted from the graphs to improve clarity.

from 6.9–50.9 h (Fig. 2). Despite variation in GPT, species-specific differences were not significant ($P > 0.51$). No significant differences in GPT were detected when the phytoplankton species were grouped into diatom, flagellate and dinoflagellate taxa ($P > 0.71$).

Assimilation Efficiency

Assimilation efficiencies of the nine-phytoplankton species are shown in Figure 3. The greenshell mussel assimilated phytoplankton with overall high rates, but average assimilation efficiency (AE) varied considerably with phytoplankton species, ranging from 55.6% to 87.7%. Overall, AEs of dinoflagellates were highest, whereas AEs of diatoms were lowest. The average efficiency with which the mussel assimilated the dinoflagellates ($84.5 \pm 6.3\%$) was significantly higher than that of diatoms ($P < 0.01$) ($61.7 \pm 11.0\%$). Similarly, mussels assimilated flagellates with significantly higher efficiency than diatoms ($P < 0.01$). However, the difference of AEs between flagellates ($77.9 \pm 6.7\%$) and dinoflagellates was not significant ($P > 0.08$). There were no

significant differences of AE between species within diatom ($P > 0.17$), flagellate ($P > 0.56$) and dinoflagellate ($P > 0.41$).

Correlation analysis showed that AE of diatoms was negatively correlated to GPT ($R^2 = -0.97$, $P > 0.11$), but AEs of dinoflagellates and flagellates were positively correlated to GPT ($R^2 = 0.1$, $P > 0.86$). If *Alexandrium minutum* is excluded, this trend is more robust ($R^2 = 0.49$, $P > 0.18$).

DISCUSSION

The pulse-chase feeding technique was used in this study to specifically address the influence of phytoplankton species on assimilation efficiency in the greenshell mussel *Perna canaliculus*. We chose to use nine phytoplankton species to represent diatoms, dinoflagellates and flagellates that are found in the mussel farming areas in New Zealand. The results have demonstrated that AE varied between phytoplankton species, but AEs of dinoflagellates and flagellates was generally higher than those of diatoms.

The GPT in our study varied between 7 and 51 h, which was independent of algal species. Control of gut retention time has been demonstrated in *Mytilus edulis* and *Cerastoderma edule* and a strong positive relationship between absorption efficiency and gut retention time has been recorded in *M. edulis* (e.g., Hawkins et al. 1990, Wang & Fisher 1996, Chong & Wang 2000). Longer retention of ingested food within the digestive tract allows for more efficient digestion and assimilation (Willows 1992), and thus maximizes nutrient gain. Although this theory is supported by our experimental data that AEs of dinoflagellate and flagellate diets for which AE was positively correlated to GPT, AE of diatoms was negatively correlated to GPT. These results suggest that AE may not always increase with increasing GPT. Similar results have also been observed from two marine bivalves in which AE of pooled diatoms and flagellates was not correlated to GPT (Li et al. 2001). The assimilation efficiency of bivalves reflects complex physiological processes within an organism and can be influenced by many physiological factors including enzymatic digestive activity, gut residence time, gut capacity and digestive synchrony (e.g., Bayne & Newell 1983, Hawkins et al. 1990, Wang & Fisher 1996, Charles & Newell 1997). The adaptive strategies of bivalves in digestive processes (Bricelj et al. 1984) may help explain the differing results. A mussel would have little benefit in withholding relatively indigestible diatoms longer in the gut for more efficient digestion. The difference of diatom-AEs may have resulted from

the variability in digestibility between the species. Relatively less digestible diatom species may be egested more rapidly. Conversely, the longer GPT of relatively digestible dinoflagellates and flagellates would have resulted in more efficiency.

Our observations demonstrated that mussels assimilated carbon from diatoms at a lower efficiency than they did from dinoflagellates and flagellates. This is probably typical for many bivalves, because the cell walls of diatoms are rigid and resistant to enzymatic digestion and physical breakdown, and diatoms also contains significantly higher quantities of inorganic matter. AEs measured in our experiments are comparable with previous studies in other bivalves. For example, Shumway et al. (1985) found that bivalve molluscs preferentially assimilated a cryptomonad flagellate over a diatom. Variations in assimilation efficiency with different algal species have been observed in other marine bivalves (e.g., Romberger & Epifanio 1981, Wang & Fisher 1996). The assimilation of some algal species can be extremely low, which would result in low energy available for growth. For example, oysters *Crassostrea virginica* could hardly digest *Platymonas suecica* (Romberger & Epifanio 1981). Results from our experiments indicated that the greenshell mussel digested algal species with a relatively overall high AE (55.6% to 87.7%) compared with the mussel *M. edulis* (7% to 86%, Wang & Fisher 1996), the oyster *C. virginica* (6% to 74%, Romberger & Epifanio 1981).

Although assimilation of the greenshell mussel have been investigated, direct comparison of AE is difficult because previous studies used either different algal species (Hawkins et al. 1999) or natural seawater (Gardner 2000) or combination of single algal species and natural seawater (Hawkins et al. 1999). To our knowledge, only one study used the same algal species (*Isochrysis*) as the present study (Marsden & Weatherhead 1999). Our measured AE (76.3%) is lower than theirs (84%). Differences in experimental designs may explain the differing results. The previous study used intertidal mussels starved for 3–12 d before experimentation. The physiological behavior may have either differed from farmed mussels or have been affected by starvation or both. Moreover, their study used the Conover technique. This technique relies on measuring gravimetric changes in the ratio of organic material to ash between food and feces, which is susceptible to weighing errors (Navarro & Thompson 1994). Therefore, it is not as sensitive as the radiotracer technique that we used in this study. Because the radiotracer technique does not require a large amount of material, it is particularly accurate when food concentration is low and consists of a high proportion of algal particles.

Selective feeding on particles of different sizes has been reported in filter feeders (Newell & Jordan 1989, Barrillé et al. 1993, Wang & Fisher 1996), but this selective behavior was only demonstrated in marine bivalves when fed with small particles. For example, experimental results by Barrillé et al. (1993) showed no change in retention efficiency of oyster (*Crassostrea gigas*) for particles larger than 3–4 μm . Wang & Fisher (1996) demonstrated that assimilation efficiency of *M. edulis* was not directly related to the particle size of different algae ranging from 2–40 μm , which is in agreement with other studies (e.g., Newell & Jordan 1983). Similarly, the size of the algal cells in our study ranged from 4–38 μm (data not showed) and was not significantly related to assimilation efficiency ($P > 0.68$). Therefore, algal sizes in this range may not be important during the digestive period and thus would not significantly affect assimilation efficiency.

We did not account for respiratory loss of ^{14}C in the present

study, which may have resulted in slight underestimates of AEs. However, the respiratory loss of ^{14}C may be negligible according to similar experiments on other mussels (e.g., Kreeger 1993, Wang & Fisher 1996) and only 0.4% of ingested food went to CO_2 (Charles & Newell 1997). Although the contribution of respired ^{14}C to AEs might be small, it is recommended that this term be included in the future measurements.

Studies on the food available to bivalve feeders in coastal waters reveal marked temporal variations in particulate matter concentration, composition and nutritional value (Bayne et al. 1993, Galois et al. 1996). Variability on a scale of days to weeks can result from episodic algal blooms and shifts in species composition. In the extensive mussel farming area of Marlborough Sounds, New Zealand, a high-frequency fluctuation of phytoplankton species composition has been observed (Mackenzie et al. 1986). For example, in early spring and summer of 1982 to 1983, microflagellates dominated the phytoplankton community (over 50%), whereas diatom species made up of less than 30% of the total biomass. In the autumn however, the diatoms dominated (>50%) (Mackenzie et al. 1986). An understanding of the influence of food type on assimilation efficiency is fundamental to validating models that predict not only greenshell mussel energetics and growth but also the capacity of the environment to support phytoplankton grazing by farmed mussels. Accurate models are essential for effective long-term farm management. There is a lack of comprehensive knowledge on assimilation efficiency and it is often assumed to be a constant or a functional response of ingested organic matter in many energetic modeling studies on farmed bivalves (Ren & Ross 2001, Ren & Ross 2005). An obvious and important aspect of the incorporation of AE into predictive models is obtaining values that are representative of the natural diet. Mussels have the ability to selectively ingest organic or high nutrient particles (e.g., Bayne & Hawkins 1990). If preferential assimilation of phytoplankton species has not been accounted for, then predictive models based on only one component of the diet such as organic content, may potentially under- or overestimate true energetics of the mussel. The present study has clearly demonstrated a

considerable difference of physiological responses of the green-shell mussel to algal types.

It should be noted that AE might vary not only with phytoplankton species but also with different life stages of bivalves. For example, the diatom *Skeletonema costatum* is an excellent food for oyster juveniles (Walne 1970) but poor for larvae of the same species (*Ostrea edulis*) that favor flagellates (Enright et al. 1986, Ferreira et al. 1990). Assimilation efficiencies of the phytoplankton species tested in our study are applicable to adult mussels. Further experiments are needed to investigate how juvenile and larval stages of the mussel respond to changes of food types.

In conclusion, the present study shows that assimilation efficiencies of adult *P. canaliculus* depend on the phytoplankton genera and/or species. This variability appeared to be related to differing digestibility of phytoplankton species caused by rigid cell walls of diatoms being more difficult for enzymatic digestion than dinoflagellates and flagellates. This finding would provide important information to the understanding of the physiological response of the mussel to the type of phytoplankton species. However, a diet of a single algal species may evoke a feeding behavior that differs from diets of multialgal species or natural seawater (e.g., Romberger & Epifanio 1981, Navarro et al. 1992, Hawkins et al. 1996). Before the results are incorporated into energetic and carrying capacity models, further experimental work should be conducted to investigate the mussel responses to mixed diets of multialgal species in field conditions.

ACKNOWLEDGMENTS

The authors thank Mark Weatherhead, Andrea Blackburn and Dave Rawlings for providing logistic supports for the experiment and Sealord Shellfish Ltd for providing mussel samples. Thanks to Magazine Bay Marina for holding the mussels. We gratefully acknowledge the valuable comments of Dr. Jeanie Stenton-Dorey and anonymous reviewers. AGEING AND METABOLISM OF *MYTILUS EDULIS*: POPULATIONS FROM VARIOUS CLIMATE REGIMES

A. A. SUKHOTIN,^{1,3*} D. ABELE² AND H.-O. PÖRTNER²

¹White Sea Biological Station, Zoological Institute of Russian Academy of Sciences, Universitetskaya nab., 1, 199034 St. Petersburg, Russia; ²Alfred-Wegener Institute für Polar und Meeresforschung, Ökophysiologie, Am Handelshafen 12, 27570 Bremerhaven, Germany

ABSTRACT The aim of this study is to elucidate the impact of age and temperature on metabolic key parameters (respiration rate and mitochondrial marker enzymes) controlling maximal size and longevity in the blue mussel *Mytilus edulis* L. from geographically separated populations of Northern European seas. Mussels from the Barents Sea attain similar maximal sizes as animals from the warmer North Sea. Young animals (<5 y) grow faster in the North Sea, however, inshore Barents Sea mussels grow rapidly even at advanced age. The slowest growth rates were found in a population exposed to strong wave action in the Barents Sea. Respiration rates followed the same age dependent pattern in mussels from all studied populations with low respiration rates in the youngest specimens followed by a rapid increase and then a gradual decline to nearly constant values in the oldest animals. When compared at a common temperature, metabolic rates only of young blue mussels (<7–8 y) are cold compensated with maximal respiration in the most Northern populations. Cold compensated metabolic activities in mussels from Northern populations may support similar patterns of maximal body size and longevity as in the more temperate Southern population.

KEY WORDS: ageing, Barents Sea, citrate synthase, cytochrome C oxidase, growth, environmental temperature, *Mytilus edulis*, North Sea, respiration rate, White Sea

INTRODUCTION

Most eurythermal marine invertebrates of the Northern hemisphere have wide latitudinal distribution and physiological differences between spatially separated populations of one and the same species can be pronounced. In times of rapidly changing regional climate regimes it is a prime concern to study the quality of physiological adaptations, especially in key species like the blue mussel *Mytilus edulis*. Low ambient temperatures slow down metabolic activity at high latitudes, and there is by now ample evidence that thermal lowering metabolic rates extends life span in ectothermal models like *Caenorhabditis elegans* (Van Voorhies & Ward 1999) or *Drosophila melanogaster* (Luckinbill 1998). However, in aquatic ectotherms observations are controversial. Some eurythermal species are distributed over wide latitudinal gradients, and, at least in northern populations, the animals tend to attain bigger body sizes and longer life spans than their southern counterparts (MacDonald & Thompson 1988, Gianniny & Geary 1992, Duchesne & Magnan 1997). In others, no tendency or the opposite trend is observed (Selin et al. 1991, Garvey & Marschall 2003). Although a growing number of publications analyze the ageing process and the influence of age on metabolism in ectotherms with infinite growth (Zolotarev & Ryabushko 1977, Fidhiany & Winckler 1998, Zielinski & Pörtner 2000, Sukhotin et al. 2002, Philipp et al. 2005, 2006), virtually nothing is known about the variation of ageing parameters within a species with a latitudinal distribution.

Latitudinal variations of metabolic rate in aquatic ectotherms were extensively studied and shaped into the hypothesis of metabolic cold adaptation, which suggests a significant elevation of metabolic rate in cold adapted species. This hypothesis has recently been challenged for Antarctic stenotherms (Clarke & Johnston 1999, Peck & Conway 2000), but it has been re-emphasized in comparative studies of temperate and subpolar,

Northern hemisphere eurytherms (Pörtner 2002a, Pörtner 2004). Notably, eurythermal cold-water animals are characterized by elevated standard metabolic rates in comparison with temperate and tropical congeneric species. The present study addresses the consequences of these patterns for the lifespans of marine bivalves by investigating metabolic changes in the course of ageing in geographically separated populations of the blue mussel *Mytilus edulis*. *M. edulis* is a eurythermal species inhabiting European coasts from the French Atlantic coast in the South to the eastern parts of the Barents Sea and the White Sea in the North. We compared growth, metabolic rates and mitochondrial key enzymes of blue mussels from the relatively warm temperate North Sea (Helgoland), the cold subArctic White Sea, where seasonal temperature variations can span up to 15°C, as well as from the cold, but thermally more stable Barents Sea (the seasonal difference in temperature is about 6°C).

MATERIAL AND METHODS

Animals

Field sampling of blue mussels *Mytilus edulis* L. was carried out in 3 main areas: (1) Barents Sea (Kola Peninsula, Yarnyshnaja Bay 69°06'N, 36°04'E), (2) White Sea (Chupa Inlet of Kandalaksha Bay, 66°20'N, 33°40'E) and (3) North Sea (at Helgoland Island, 54°11'N, 7°53'E) (Fig. 1a). Salinity of surface waters range from about 24 ppt in the White Sea to 28–32 ppt in the Barents and the North seas. The three selected sampling locations form a cline of temperature conditions. The warmest is the North Sea, whereas the White and the Barents Seas are characterized by far lower winter and summer temperatures, respectively (Fig. 1b). At each site dense or dispersed settlements of *Mytilus edulis* are found in intertidal and upper subtidal zones. Sampling was performed from intertidal dense mussel beds at about 0.7–1 m above 0 tidal level in each of the three sampling areas. The mussel bed in Yarnyshnaja Bay (Barents Sea, BSi) is situated in the innermost part of a narrow bay, which penetrates about 6 km into the Kola Peninsula shoreline and is thus protected from wave action. In the White Sea sampling

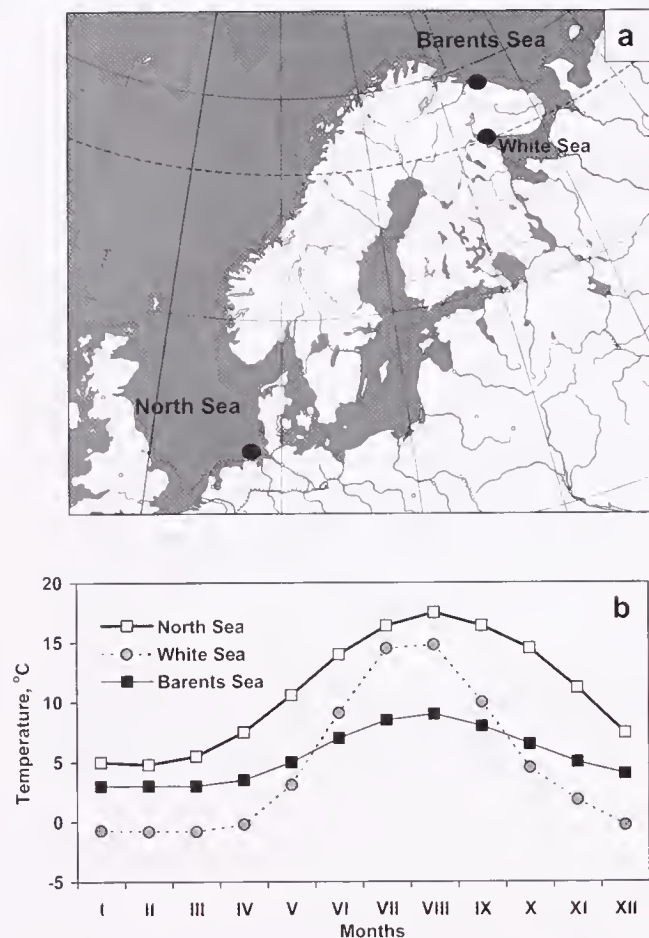

Figure 1. Map of study area and sampling sites of mussels (a) and monthly average temperature in the North Sea (<http://hah.wdc-mare.org>), Barents Sea (Matishov et al. 1998) and White Sea (Babkov, 1982).

area (WS) *Mytilus edulis* forms a dense multilayer population on the southern shore of a small island, which is also sheltered from direct wave action, whereas exposed to strong tidal currents. In the North Sea (NS) mussels were collected from the rocky intertidal on the NW coast of Helgoland Island. This site is exposed to wave action at N to NE wind directions.

Mussels were collected in October (BSi and WS) and November (NS) 2002. Sea water temperature was +5.5°C and +9°C, respectively. Furthermore, mussels were sampled from an intertidal population situated in the outer part of Yarnyshnaja Bay of the Barents Sea (BSO). This area is exposed to strong wave action. In addition, a small sample of mussels from the most Eastern part of the Barents Sea was kindly collected by Dr. P.P. Strelkov. These mussels were sampled from subtidal population in 6-m depth near the Vajgach Island (Barents Sea, Novaya Zemlya Archipelago, 69°44'N, 59°30'E) in August 2002 at a water temperature of +3°C.

Molluscs from all sites were transported alive to the Alfred-Wegener Institute (Bremerhaven, Germany) and maintained in aquaria at 30 ppm salinity and +5.7°C temperature. Age was determined for all mussels by counting the rings of winter growth delays on the outer shell surface. This method has previously been verified in studies carried out in the White Sea by comparing the number of internal rings and seasonal growth of individually marked mussels (Chemodanov & Maximovich 1983, Sirenko &

Saranchova 1985). Respiration measurements were performed in January 2003.

Growth

Growth rings of mussels from all four populations were measured from the umbo to the most distant edge of the shell to the nearest 0.1 mm for reconstruction of the growth history of mussels. Linear growth of mussels was approximated using the von Bertalanffy model

$$L_t = L_{\infty} \cdot (1 - \exp^{-k \cdot (t - t_0)}),$$

in which L_t is length (mm) at the age t (years), L_{∞} , k and t_0 are constants.

Experimental Procedure

Mussels from all populations were sorted by age with considerable variability in animal size within each age class. The BSi group included age classes from 3–15 y (12 and 14 y age classes were missing) ranging in size from 0.187–4.740 (mean = 1.03) g wet tissue weight. The BSo group was represented by 4–8-y-old mussels (0.095–0.479, mean = 0.29 g wet tissue weight). Mussels from the White Sea (WS) were 1–10 y old (0.046–2.40, mean = 0.72 g wet tissue wt) whereas the North Sea sample (NS) comprised animals from <1 to 11 y of age (0.206–4.036, mean = 1.58 g wet tissue wt). Vajgach sample (Vajgach) was represented by only 8 specimens 5–11-y-old (0.249–1.374, mean 0.75 g wet tissue wt). Mussels from this sample were used only for respiration rate measurements.

Oxygen consumption was measured at +5°C in closed 150–200 mL respirometers, containing 1–6 mussels. Oxygen concentration was monitored using Clark type oxygen electrodes (Eschweiler, Kiel, Germany). After the measurements mussels were cut open, gills were dissected, blotted dry on tissue paper, weighed to the nearest 0.1 mg and deep frozen in liquid nitrogen for further analyses of enzyme activities. The residual tissues were also weighed. Respiration rate was expressed in $\mu\text{mol O}_2 \text{ g}^{-1} \text{ tissue wet wt h}^{-1}$.

Analyses

Citrate synthase (CS, EC 2.3.3.1) activity was measured spectrophotometrically at 412 nm using an enzymatic test (Sidell et al. 1987). Powdered tissue (about 100 mg) was homogenized in 75 mM Tris+1mM EDTA buffer (pH 7.6) at a 1:9 w/v ratio. After centrifugation (10 min, 9,500 g, at 0°C) CS activity in the supernatant was measured in 100 mM Tris-HCl buffer (pH 8.0) containing 20mM acetyl-CoA, 20 mM oxaloacetate and 5 mM DTNB. Absorbance was monitored at 412 nm using a spectrophotometer (LKB Pharmacia) with cuvettes thermostatted at +25°C.

Cytochrome C oxidase (COX, EC 1.9.3.1) activity in mussel gill tissue was determined according to Hardewig et al. (1999). Powdered tissue (1:9 w/v) was homogenized in 20 mM Tris-HCl +1mM EDTA + 0.1% Tween 20 buffer (pH 7.4). Enzyme activity was measured in the assay buffer (20 mM Tris-HCl, pH 8.0 + 0.5% Tween 20 + 50 μM reduced cytochrome c) at +25°C. The decrease of absorbance was determined spectrophotometrically (LKB Pharmacia) at 550 nm. Cytochrome C, dissolved in 20 mM Tris-HCl, pH 8.0 was reduced by sodium dithionite, which was removed by gel filtration in a Sephadex G-25 column. Enzyme activities were expressed in $\text{U g}^{-1} \text{ tissue wet wt}$.

Calculations and Statistics

One-way ANOVA was used to compare densities, biomasses, respiration rates and enzyme activities between populations. Post-

hoc comparisons were made by Tukey HSD Test for unequal N. Age effects on respiration rates and enzyme activities were tested by Kruskal-Wallis nonparametric test. Age distributions in the studied populations were compared by the Chi-square test. The F-test was used for comparisons of linear growth equations in different samples.

RESULTS

Growth

Mussels from NS and WS populations grew rapidly during the first 4–5 y but growth tended to level off hereafter (Fig. 2). Molluscs from the Barents Sea displayed similar growth strategies in both populations until the 5th year, when animals from the open shore (BSO) slowed their growth, whereas mussels from the sheltered part of the bay (BSi) continued intensive growth until the age of about 10 y, whereafter a decrease in growth rate was observed. In terms of absolute shell length increment, mussels from the North Sea had the fastest growth of all populations in the first 2–3 y after settlement, attaining over 30-mm body length during young age. Hereafter their growth rate diminished to that of mussels from the other sites. The most rapid growth at advanced age (over 5-y-olds, beyond 20-mm body length) was found in the Barents Sea population from the protected site in Yarnyshnaja Bay (BSi). Pairwise comparisons showed that growth curves of mussels from the White Sea (WS) and from the open part of the Yarnyshnaja Bay (BSO, Fig. 2) did not differ statistically ($P = 0.246$, F-test). Both demonstrated an abrupt decrease of growth rate after reaching 5 y of age. Growth rates of BSi mussels differed significantly from both BSO and WS specimens at $P = 0.0012$ and $P < 0.001$, respectively, whereas NS animals differed from all others at $P < 0.001$ (F-test).

Respiration Rate

The effect of body size on respiration was approximated using 5-y-old individuals from all 3 stations, because this age class was in the middle of the age range and also one of the most abundant (except for the juveniles) in the studied populations (unpublished data). Respiration rate (RR , $\mu\text{mol O}_2 \text{ g}^{-1} \text{ wet wt h}^{-1}$) of 5-y-old *M. edulis* decreased as a function of tissue wet weight (W , g)

$$RR = 3.8 W^{-0.356} \quad (r = -0.838, p < 0.001, N = 15).$$

The obtained power coefficient (-0.356) was then used for a weight correction of the respiration data to a mean wet tissue weight ($= 1.00 \text{ g}$) for comparisons between mussels of different ages and populations. The correction was as follows $R_{\text{corrected}} = R_{\text{observed}} \times (1/W)^{-0.356}$.

Although the Vajgach population was subtidal and therefore differed from the other populations, it was included in the inter-population comparisons of mussels' respiration as the most distant outpost with the lowest ambient temperatures. The factor "population" had a significant ($P < 0.001$, ANOVA) effect on weight-corrected respiration rates. Figure 3a presents respiration rates of mussels from 5 populations as means of all ages. Respiration increased in the following rank order: NS < WS = BSi = BSo < Vajgach. Compared at a common experimental temperature of 5°C, NS mussels were characterized by significantly ($P < 0.01$, Tukey HSD) lower respiration rates than their more northern counterparts, whereas Vajgach animals exceeded NS, WS and BSi ones by respiration at $P < 0.05$. The factor "population" affected mussel respiration in the separate age classes: 2, 4, 5, 6 and 7 y ($P < 0.05$, Kruskal-Wallis test), whereas at ages 1, 3 and older than 7 y the difference between populations was below significance (Fig. 3b).

Because age classes in Vajgach sample were represented by too

Figure 2. Von Bertalanffy growth curves in mussel populations. NS, North Sea; $L_{\infty} = 62.8 \cdot (1 - \exp^{-0.197(t+0.34)})$, $n = 215$, BSi, Barents Sea; innermost (sheltered) part of the bay; $L_{\infty} = 412.0 \cdot (1 - \exp^{-0.014(t-1.380)})$, $n = 194$, BSo, Barents Sea; outer (open) part of the bay; $L_{\infty} = 126.2 \cdot (1 - \exp^{-0.035(t-1.206)})$, $n = 30$, WS, White Sea; $L_{\infty} = 39.3 \cdot (1 - \exp^{-0.184(t-1.160)})$, $n = 238$. Data are mean \pm SE.

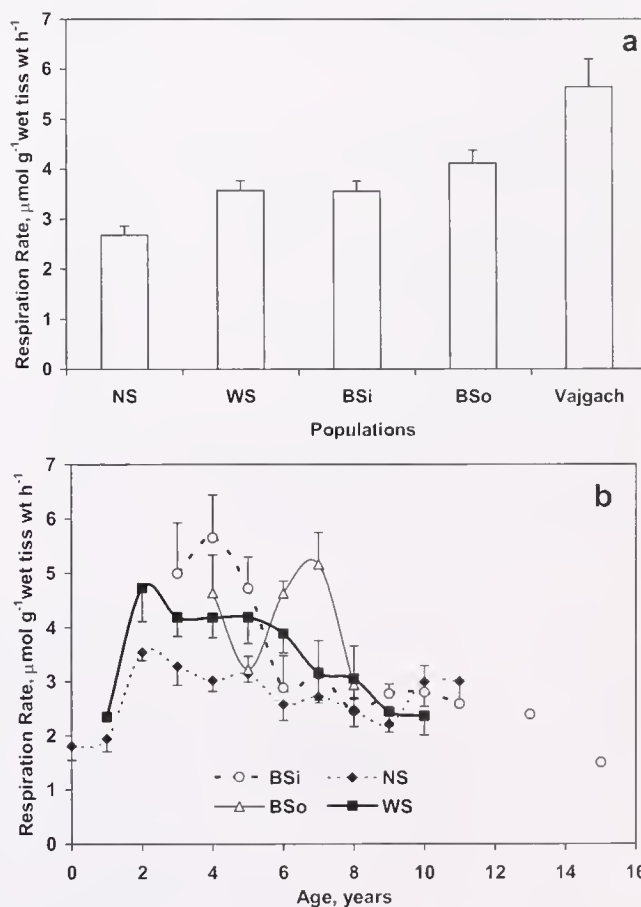

Figure 3. Respiration rates of mussels from studied populations—all age classes combined together (a) and in different age classes (b). NS, North Sea; BSi, Barents Sea; innermost (sheltered) part of the bay, BSo, Barents Sea; outer (open) part of the bay, WS, White Sea; Data are mean \pm SE, evaluated at 5°C.

few specimens this population was not included in the analysis of age influence on respiration. Age effects on mussel respiration rates were significant at $P = 0.026$, $P = 0.047$, $P = 0.004$ and $P = 0.010$ (Kruskal-Wallis test) for BSi, BSo, NS and WS populations, respectively (Fig. 3b). The shape of the curves describing the age dependence of respiration rates in mussels was similar for NS and WS molluscs. In these groups respiration rates were low at young age (0–1-y-old) followed by a significant increase in 2-y-old specimens. Older mussels were characterized by a gradual decrease of respiration with age, with constant rates in age classes 3–5 in both WS and NS molluscs. The oldest (10–11-y-old) specimens from the NS displayed insignificantly higher respiration rates than 6–9-y-old animals from that same site. However, the sample size was too small for meaningful statistical analyses.

The respiration rate of the youngest mussels in the BSi group (3-y-old) was somewhat, but nonsignificantly, lower than that of 4-y-old specimens, which displayed the highest respiration rates in this population. A rapid 2-fold decrease in respiration rate was recorded between age classes 4 and 6 followed by a gradual decline to the lowest values seen in 15-y-old specimens.

The age range of mussels from the BSo population was much narrower than that of the other populations and included only age classes 4–8 y. Animals older than 8 y were never found on the BSo site. On the other hand, young specimens (0–3-y-old) were too small to be included in the experiments (mean shell length of 3-y-olds from BSo was 6.1 mm). The respiration rate of BSo mussels was similar in all age classes

Enzyme Activities

CS activity in gill tissue of *M. edulis* varied from 2.15–8.24 U g^{-1} wet tissue wt, whereas COX activity was in the range 0.44–1.65 U g^{-1} wet tissue wt. The activity of both enzymes appeared positively correlated (Spearman $R = 0.517$, $n = 125$, $P < 0.001$) (Fig. 4). Size effects on the activity of citrate synthase and cytochrome C oxidase were tested using regression (enzyme activity vs. body mass) analyses in separate age groups of different populations. No significant trend was found for either CS or COX.

Age of the mussels had no influence on either CS or COX activities (Kruskal-Wallis test) (Fig. 5a). The factor "population" significantly affected the activity of both enzymes (ANOVA, $P < 0.01$ for CS and $P < 0.001$ for COX) resulting in a decrease in activity in the order $\text{NS} > \text{WS} > \text{BSi} \geq \text{BSo}$ (Fig. 5b). NS mussels differed from both Barents Sea populations ($P < 0.05$, Tukey HSD

Figure 4. Relationship between cytochrome C oxidase and citrate synthase activities in mussels analyzed at 25°C.

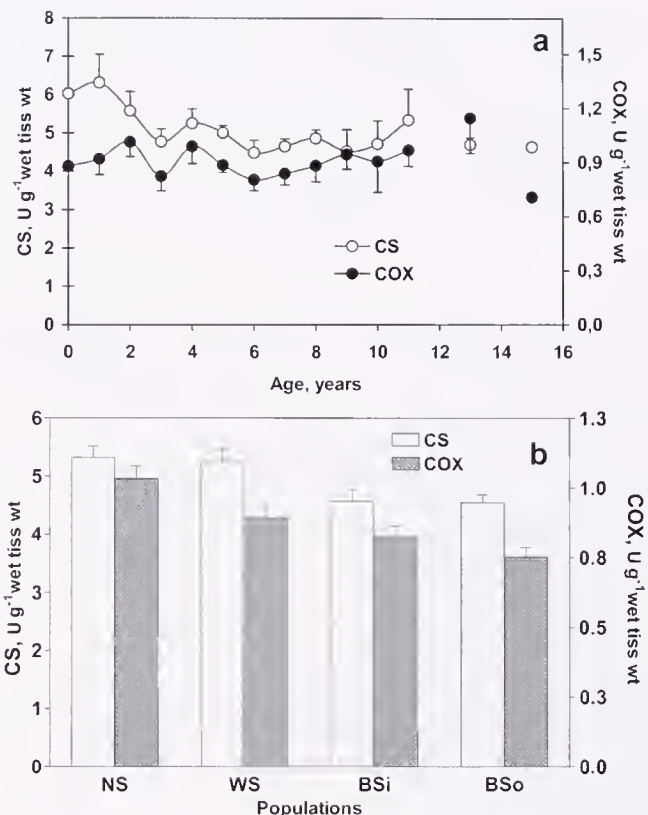

Figure 5. The effect of age (a) and population (b) on cytochrome C oxidase and citrate synthase activities in mussels (enzyme activities analyzed at 25°C).

test) with respect to COX and from BSi ($P < 0.05$, Tukey HSD test) with respect to CS activities.

DISCUSSION

Growth patterns and maximal size observed in the NS and WS populations are typical for mussels from intertidal habitats of the respective areas (see for comparison, for the North Sea: Craeymeersch et al. 1986; Munch-Petersen & Kristensen 2001, for the White Sea: Savilov 1953, Maximovich 1989). On the exposed rocky shore (BSo) mussels colonize crevices in the rocks, where they are protected from strong wave action. Maximal size of mussels in this habitat is obviously limited by the sheltered space available, because animals sticking out from crevices are mechanically removed by waves and winter ice. Strong hydrodynamic action on open shores provide better conditions for growth of mussels from different species than sheltered bays, however, in extreme cases growth on exposed habitats is inhibited and longevity is reduced (McQuaid & Lindsay 2000, Steffani & Branch 2003). Growth of mussels from the sheltered BSi population until the animals reach about 20-mm shell size at 5–6 y. Older BSo animals grow significantly slower than BSi mussels and have only 2 y of further life expectancy. Thus, maximum size and longevity of mussels from the exposed intertidal of the Barents Sea are likely determined by wave action and firmly limited to a maximal size of 30–35 mm reached after 8 y.

In contrast, animals from BSi do not seem to be limited by any mechanical factor and reach maximal old age and maximal attain-

able size among all studied populations. Although before 3–4 y of age they grow slower than NS and WS mussels with smaller annual growth increments, they keep growing by about 5–6-mm per year until they are about 13-y-old and, eventually, outgrow and outlive mussels from all other populations of this study.

NS mussels exceeded all other populations in shell size within each age class. This difference is grounded in a significant distinction in body size reached by the end of their first growth season in all four populations. *Mytilus* spat in the NS had grown to a mean size of 12.9 mm by the beginning of winter, whereas newly settled mussels in the WS, BSi and BSo attained on average 1.1, 0.81 and 0.60 mm during their first growth season. This parameter (the size of the first ring) depends on two factors: growth rate and duration of the growth season. In the North Sea (at Helgoland, see Sprung, 1983) *Mytilus* settlement starts already in midMay resulting in a 4–5 mo long initial growth season for the spat in a relatively warm sea. In the White Sea and the Barents Sea mussels spat settles in August and even later, leaving not more than 1.5–2 mo for growth before seasonal cooling starts.

According to Bergmann's rule (originally elaborated for mammals and birds, Ray 1960) animals tend to increase their average body size with increasing latitude. Among Northern hemisphere aquatic ectotherms following this rule are fishes *Squalus mitsukurina* (Taniuchi et al. 1993), and the gastropod mollusc *Acanthina punctulata* (Gianniny & Geary 1992). Some weaker but significant trends to grow bigger at higher latitudes are recorded for the giant scallop *Placopecten magellanicus* (MacDonald & Thompson 1988) and the deep-sea gastropod *Troschelia berniciensis* (Olabarria & Thurston 2003). There are however numerous deviations from this rule (e.g., Gilbert 1973, Selin et al. 1991, Duchesne & Magnan 1997, Garvey & Marshall 2003). The largest specimens of mussels found in our samples from the NS and BSi populations were 60.0 and 71.4 mm length (4.32 and 4.74 g wet tissue weight), respectively. Although mussels from the northern population (BSi) in our study reach the biggest shell size, they attain only similar maximal soft body masses as NS mussels. Therefore, our data do not support Bergmann's rule as well as the expectations of slower growth and longer life of mussels from Arctic compared with temperate populations.

Age effects on respiration rates of mussels were studied in four different populations over a wide age range from 0–15 y. In all populations a similar pattern was observed, namely, low respiration rates in the youngest specimens followed by a rapid increase and then a gradual decline to nearly constant and similar values in the oldest specimens at each site. Initial low respiration values may relate to sexual immaturity of the young animals. It has been shown (Maximovich 1985) that *M. edulis* in the White and the Barents Seas attain sexual maturity only beyond 15–20 mm shell length (50–100 mg wet tissue weight). 2-y-old mussels from the WS population included in the analysis displayed 160–340-mg tissue wet weight, whereas 1-y-old mussels ranged between 40 and 60 mg. The fact that 2-y-olds were already mature, whereas 1-y-olds were immature can explain the difference in respiration rates between mussels of these two age classes. According to Sprung (1983), mussels from Helgoland become sexually mature after 1 or 2 y, which explains low respiration rates in 0–1-y-old specimens from the NS. The youngest mussels (3 and 4-y-old) studied in both Barents Sea populations were mature and displayed high respiration rates.

The age-related pattern of respiration rates is common among all four studied populations. Sexual maturation is accompanied by

an increase of weight specific respiration, which is followed by a more or less pronounced decrease of respiration at older age. It is interesting that despite the almost 2-fold difference in maximum lifespan observed in the studied populations (8 and 15 y in BSo and BSi, respectively), the age window of "metabolically most active" mussels is the same in all populations (from the age of sexual maturity to 6–7 y) (Fig. 3b).

A general decrease of weight specific metabolic rate in the course of ageing is reported for homeotherms and insects (see for review McCarter 1995), however, with few exceptions (O'Connor et al. 2002). Data on age-dependence of metabolic rate in infinitely growing species are controversial. Mere age effects on respiration rate (not linked to the influence of body size) were reported for bivalves *Crenomytilus grayanus* (Zolotarev & Ryabushko 1977), *Argopecten irradians irradians* (Bricelj et al. 1987), *Mytilus edulis* (Sukhotin & Pörtner 2001) and fish *Cichlasoma nigrofasciatum* (Fidhiany & Winckler 1998). However, in other studies this effect was poor or not seen at all (Pérez Camacho et al. 2000, Sukhotin et al. 2002, 2003). This study shows that age effects on metabolic rate of mussels are not straight forward (the older the animal, the lower the metabolic rate). There can be periods with a strong effect of age on respiration (e.g., an increase after maturation or a rapid decrease after 6–7 y of age) and also time intervals when metabolism is virtually independent of age (e.g., in the most metabolically active and also in the oldest specimens). Therefore, comparisons of selected age classes in latitudinal comparisons, seeking for an effect of environmental temperature on metabolic rates may lead to erroneous interpretations. Further, our data suggest that the age-related decline in respiration is more pronounced in cold-adapted subArctic animals (BS and WS) than in North Sea mussels. Moreover, in warm-acclimated (summer) animals (Sukhotin et al. 2002; 2003) the age effect may not appear as pronounced as in late autumn (this study) and winter.

Respiration rates of mussels from the investigated populations are indicative of metabolic cold compensation in *Mytilus edulis* from Northern latitudes. This compensation of respiratory capacity in cold adapted ectotherms from the Northern hemisphere is achieved by an increase of mitochondrial density or inner membrane surface area as well as mitochondrial capacity (Tschischka et al. 2000, Sommer & Pörtner 2002, 2004). Mussels from intermediate reproductive age classes from the more northern populations had higher specific respiration rates than those from the North Sea. By contrast, old and presumably also very young mussels had lower and uniform respiration rates in all populations so that population differences were abolished in the old animals (Fig. 3b). In other words, cold adaptation, specifically latitudinal differences in metabolic rates according to different temperatures manifests especially in the most metabolically active specimens, possibly because of active somatic growth and substantial reproductive effort, which are costly in terms of assimilated energy. When combined, both findings support the view that in the Northern *Mytilus* populations lifetime energy expenses peak early in life to support reproductive output in young animals, whereas metabolic activity declines rapidly thereafter. This may be an adaptation to the harsh environmental conditions and may also reflect an age-related decrease of energy demands for somatic growth and reproduction, until a baseline level of energy turnover is reached as required for maintenance that allows no further reduction in the old animal.

Weight specific activities of metabolic enzymes as citrate synthase and cytochrome C oxidase often vary between warm and cold adapted mollusks or between summer and winter specimens

in one and the same population. Interestingly, whole animal respiration in our study did not follow the same trend as the mitochondrial key enzymes in gills. Enzyme activities in gills were highest in the North Sea population (25°C assay temperature) but whole animal respiration at 5°C was lower at Helgoland than in WS and BS animals. Higher enzyme activities at low whole animal respiration rate would suggest higher mitochondrial densities or capacities in gills of the warmer North Sea animals despite low respiration rate measured at 5°C. This apparent contradiction might suggest that the metabolic requirements in gills vary independently from those of the whole animal. It appears conceivable that food demand and associated gill activity are high at the higher temperatures of the North Sea such that gill metabolic capacity is set high. Moreover, according to the temperature regime seen at Helgoland roads (Wiltshire & Manly 2004: 3°C to 20°C, mean $T = 9^\circ\text{C}$) the temperature applied during respiration analyses is low for Helgoland indicating that metabolic rate was measured at the low end and enzyme capacities were analyzed beyond the high end of the thermal window. Future analyses should compare mussel metabolism and enzyme activities at the same and within the range of habitat temperatures.

Aerobic enzyme capacities in other invertebrates have been found to vary in line with the cost of cold eurythermy hypothesis (Pörtner et al. 2000, Pörtner 2004). Among scallops, COX activity ranged significantly higher in *Aequipecten opercularis* from the warmer Irish Sea than in cold adapted stenothermal *Adamussium colbecki* from the high Antarctic, whereas CS activities were similar in both species (Philipp et al. 2006). In contrast, cytochrome C oxidase (COX) activity was 10-times higher during summer in cold adapted eurythermal lugworms *Arenicola marina* from the White Sea at 6°C than in North Sea specimens measured at 11°C (Sommer & Pörtner 2002). Seasonal influences may modulate this picture. Sommer and Pörtner (2004) and Keller et al. (2004) found that mitochondrial respiratory capacity was significantly higher in prespawning and lower in postspawning summer animals than in

winter. Concomitantly, CS activities in North Sea lugworm tissue during summer versus winter were equal prespawning or lower postspawning. A seasonal comparison of the related horse mussels, *Modiolus modiolus*, (Mytilidae) from shallow subtidal environment (10-m depth) of New Hampshire, Isle of Shoals, United States (Lesser & Kruse 2004) found somewhat but significantly higher respiration in summer than winter animals, however, again with CS concentration per g tissue significantly increased in the winter. This may reflect reduced whole animal respiration rates caused by metabolic depression in winter, whereas enhanced CS levels and COX activities during winter (Lesser & Kruse 2004) are in line with elevated capacities of mitochondria in seasonal cold and may also meet additional metabolic requirements on top of supporting mitochondrial capacity (Pörtner 2002b).

In conclusion, the compensatory increase of metabolic rate in cold adapted Northern hemisphere mussels manifests especially in the most metabolically active individuals and is less apparent at advanced age. Our data suggest compensation for latitudinal cold during summer in blue mussel *Mytilus edulis* Northern populations. Cold compensation is mostly reflected in active whole animal respiration rates, in line with the cold eurythermy hypothesis (cf. Pörtner et al. 2000, Sommer & Pörtner 2004). According to our data, growth and longevity in blue mussels relate to temperature variability within the climatic range covered in this study as well as to local environmental factors. Similarity of maximal life spans of mussels from latitudinally separated populations can be explained by similar metabolic rates at ambient temperature caused by metabolic cold compensation in animals at high Northern latitudes.

VALVE-GAPE RESPONSE TIMES IN MUSSELS (*MYTILUS EDULIS*)—EFFECTS OF LABORATORY PRECEDING-FEEDING CONDITIONS AND *IN SITU* TIDALLY INDUCED VARIATION IN PHYTOPLANKTON BIOMASS

HANS ULRIK RIISGÅRD,* JOHAN LASSEN AND CHRISTINA KITTNER

Marine Biological Research Centre, University of Southern Denmark, Hindsholmvej 11, DK-5300 Kerteminde, Denmark

ABSTRACT Many physiological processes in bivalves are influenced by the valve opening state and thus the valve opening-closing response times of the experimental animals. Controlled laboratory studies using underwater video camera recording of valve-gape responses of mussels (*Mytilus edulis*) to presence or absence of algal cells in the ambient water have revealed that valve opening and closing responses are strongly influenced by the preceding feeding conditions. The observations indicate that the period during which mussels may “learn” or “forget” to respond to the presence or absence of algal cells can last for weeks in the laboratory. Further, the critical algal concentration below which mussels close their valves has been identified to be about 700 *Rhodomonas* sp. cells mL⁻¹, or 0.9 µg chl *a* L⁻¹. Such knowledge is essential for making allowance for possible deviation from natural-response times in mussels kept in the laboratory previous to experimental physiological studies. *In situ* simultaneous registrations of water flow, chl *a* and valve-opening degree of mussels were made within a dense mussel bed in a shallow, tidally dominated inlet to a Danish fjord. Phases of strong tidal flow brought ample supply of phytoplankton to the mussel bed, and it was observed that concentrations higher than about 1 µg chl *a* L⁻¹ in the near-bed layer stimulated the mussels to keep their valves wide open, whereas tidal slack with slow flow resulting in near-bed concentrations below 1 µg chl *a* L⁻¹ caused by grazing by the mussels, after some time led to shell closure, or reduced valve gapes of the mussels. The valve opening time from opening degree 50% to 100% and the valve closing time from opening degree 100% to 50% in response to variation in near-bed chl *a* concentration were on average 59 ± 22 and 50 ± 19 min, respectively, which is considerably faster than observed in unfed mussels in the laboratory.

KEY WORDS: feeding activity, response to phytoplankton, valve gape, feeding activity, grazing impact

INTRODUCTION

Many physiological processes in bivalves are strongly influenced by the valve opening state and thus the valve opening-closing response times of the experimental animals (Riisgård 2001b). Filter-feeding bivalves are able to sense the presence of suspended food particles in the ambient water, and this sensitivity is reflected in the gape of the valves (Jørgensen 1975). The behavioral valve-opening repertoire ranges from closed valves and retraction of mantle edges and siphons to fully open valves accompanied by extended mantle edges and siphons (Jørgensen et al. 1988). Under optimal conditions, bivalves filter the ambient water at a maximum rate and under sub optimal environmental conditions, including low or (very) high concentrations of phytoplankton, the valve gape is reduced and the mantle edges retracted (Riisgård & Randlov 1981, Jørgensen et al. 1988, Riisgård, 1991; 2001a, Clausen & Riisgård 1996, Newell et al. 1998; 2001, Dolmer 2000a; 2000b, Riisgård et al. 2003, van Duren et al. 2005, Lassen et al. 2006). Although mussels in nature may often experience phytoplankton concentrations below the threshold level, the valve gape opening-closing response to natural variations in phytoplankton biomass in nature has so far been unobserved.

In algal clearance experiments with blue mussels, *Mytilus edulis*, we have often over the years observed that when mussels are fed algal cells for some hours every day during a period of up to one week, as has been the case during many student laboratory exercises, both the opening and closing response apparently become faster than observed on mussels starved for some days—or sometimes weeks—previous to the first clearance experiments. These observations draw attention to the importance of the previous feeding history of the bivalves. More knowledge on the response times in mussels will improve our understanding of the role of mussels for the energy flow in highly dynamic systems. In such

systems, the opening-closing-response times to presence/absence of food may potentially limit ingestion and the grazing impact on phytoplankton. Awareness of response times is also important when interpreting (e.g., observed correlations between low food concentrations and clearance rates in mussels). On shorter time scales (minutes to hours) the mussel response times may cause hysteresis and mask the underlying functional response of clearance rate to food concentration.

In the present work we first in controlled laboratory experiments examined if mussels are able to lose and regain the ability to respond promptly to absence and presence of suspended algal cells in the ambient water. Such knowledge about “memory/learning/forgetting” in filter-feeding bivalves may be essential for making allowance for possible deviation from natural-response times in animals kept in the laboratory for shorter or longer times previous to physiological experiments.

Next, in field studies we examined the interactions between water flow, near-bed phytoplankton biomass and valve gape opening-closing response times of mussels in a dense bed. The study site, the narrow inlet to a shallow fjord, was chosen because of a predictable water-flow regimen created by the tide. Because of a high area-specific population filtration rate, a considerable variation in the chlorophyll *a* concentration could be expected within a half-tidal period. Therefore, the mussels are likely to be wide open during strong-flow periods with ample supply of phytoplankton, in contrast to periods with temporary tidal slacks and low supply rates of phytoplankton, where reductions in valve-gapes could be expected.

MATERIALS AND METHODS

Laboratory Studies

Blue mussels, *Mytilus edulis*, were collected in the southeastern part of Kerteminde Fjord (Fyn, Denmark) in August 2003, January

*Corresponding author. E-mail: hur@biology.sdu.dk

and May 2004, and brought to the nearby Marine Biological Research Centre where all experiments were conducted. In feeding experiments, mussels in aerated aquaria were offered suspended algal cells *Rhodomonas* sp. (almost spherical, about 6.3 μm in diameter) that are 100% efficiently retained by the gills of *M. edulis* (Möhlenberg & Riisgård 1978). The algal cell concentration was measured by means of an electronic particle counter (Elzone 5380) by taking 15 mL water samples for analysis. All experiments were conducted at naturally low algal concentrations between 1,000–4,000 *Rhodomonas* sp. cells mL^{-1} , equivalent to about 1–5 $\mu\text{g chl } a \text{ L}^{-1}$ (Riisgård et al. 2003). In short-term laboratory experiments, the valve gapes of mussels were monitored by means of a digital camera taking a picture every 10 min. In long-term laboratory experiments, the valve gapes were monitored by means of an underwater video camera (SONY TRV25) recording the mussels for 2 s every 5 min. The individual valve gape was measured as the distance between the shells at the center of the exhalant opening and subsequently expressed as percentage of maximum distance recorded.

To study whether the opening-closing responses of the mussels and their duration are dependent on preceding feeding conditions a number of feeding/starvation experiments were performed. In one series of experiments, *Mytilus edulis* (Group #1, Table 1) were placed in an aerated aquarium with 1.2- μm filtered seawater (20 psu) and the temperature was kept constant (Hetofrig cooler/heater) at the natural (field) acclimation temperature of the mussels (19.6°C). Afterwards the mussels were fed about 3,500 *Rhodomonas* sp. cells mL^{-1} for 2 h. The following day (Day 1) *Rhodomonas* sp. cells were repeatedly added to the aquarium and filtration rate measurements were performed under simultaneous monitoring of the valve gape of the mussels during the opening phase (0% to 80% of maximum registered valve gape during the whole experiment). After 5 h feeding, the mussels were separated into two groups (Group #2A and Group #2B, Table 1) and placed in two aerated aquaria with filtered seawater and constant temperature (19.6°C). For the next 4 days (Day 2 to Day 5) filtration rate measurements were performed while simultaneously monitoring the valve gapes of mussels in Group #2A, which were fed *Rhodomonas* sp. cells for about 5 h d^{-1} . Group #2B was starved in the same period. On Day 6 the valve-gape opening response was recorded in both Group #2A and Group #2B. *Rhodomonas* sp. cells were repeatedly added to the two aquaria with the two groups, and the valve gapes were monitored until all mussels were maximally open. Then the algal supply was subsequently stopped and the valve-gape closing response to decreasing algal concentration (<1000 cells mL^{-1}) was recorded. When the mussels had reduced the algal concentration below the detection level of the electronic particle counter (about 100 *Rhodomonas* sp. cells mL^{-1} ; Riisgård

et al. 2003) further water sampling for particle analysis was ceased whereas the monitoring of valve gape continued until all mussels had closed their valves. During the following 13–14 days both groups of mussels starved whereupon, on Day 20 and Day 21 for Group #2A and Group #2B respectively, the valve-gape opening closing response was again registered.

In another series of experiments, the valve gape opening-closing response of mussels caused by presence/absence of algal cells was also recorded during periods with continuous algal supply followed by starvation periods without algal supply. The experimental period lasted for 68 and 50 days for Group #3 and Group #4 respectively (Table 1). Supply of algal cells was established from Day 1 to Day 38 for Group #3, and from Day 1 to Day 28 for Group #4, whereas long-term starvation was established from Day 38 to Day 68 for Group #3, and from Day 28 to Day 50 for Group #4.

Filtered seawater was continuously flowing through a strongly aerated aquarium with mussels. A dosing pump ensured constant addition of *Rhodomonas* sp. so that a well-defined steady-state level, corresponding to a natural phytoplankton concentration of 1.3–2.5 $\mu\text{g chl } a \text{ L}^{-1}$ was established (cf. Riisgård & Randlov 1981, Clausen & Riisgård 1996). The valve opening-closing response to presence/absence of algal cells was studied by stopping the dosing pump and the through-flow of seawater. The subsequent decrease in algal concentration caused by the filtering mussels was measured until the concentration was reduced to about 500 cells mL^{-1} . Then, by means of the dosing pump, this concentration level was maintained until all mussels had noticeably closed or reduced their valves. The duration of this closing response was defined as the time from when the concentration was 800 *Rhodomonas* sp. cells mL^{-1} (fully open mussels) to the time when the mean valve gape was reduced to 50% of the maximum registered during the preceding steady-state period. Then subsequently, the feeding conditions were resumed by switching on the algal dosing pump and the through-flow of filtered seawater and the immediate valve gape opening response recorded. The duration of the opening response was defined as the time from addition of algal cells after a short starvation period until the mean valve gape of the mussels reached 80% of the valve gape registered during the preceding steady-state. The long-term feeding period was succeeded by a starvation period to reveal if the mussels had changed the duration of the opening/closing response. To check this, the algal dosing pump was switched on for some hours to re-establish steady-state before the valve gape opening/closing response was recorded as previously described.

The experimental periods with added algal cells resulted in some growth of the mussels (increase in shell length of 0.2 and 0.7 mm in Group #3 and Group #4 respectively) and thus in an increased filtration rate, but a constant steady-state algal concentration was ensured by adjusting the dosing pump. Shell length and flesh dry weight (24 h, 110°C) were determined for all mussels after the experiments (Table 1).

Field Studies

The mussels, *Mytilus edulis*, studied in the present work formed a dense bed in the narrow inlet of Kerteninde Fjord, where a semidiurnal tide (amplitude ± 0.2 m) forces a strong, alternating in- and outgoing current (Fig. 1). In 2002 the mussel bed was overgrown by dense macro algae (*Fucus* sp.).

During the summer of 2002, simultaneous registrations of wa-

ter elevation, current speed, chlorophyll a (chl a) concentration and valve gapes of mussels were carried out as 10 one-day studies at different selected locations on the shallow north-western part (Site 1: field-study days #1 to #6, and #10), and in the somewhat deeper middle part (Site 2: field-study days #7, #8, and #9, see Fig. 1) of the mussel bed. The water elevation was registered in the fjord-inlet about 400 m from the mussel bed by means of a CTD (Aquamat). In all cases, the current speed, chl a and valve gapes were registered on the same spot (with half a square meter) on the selected locations. The current speed was registered by means of a current propeller (Hydrobios) fixed at 20-cm height Site 1 and 50-cm height above the mussel bed at Site 2. The chl a (chl a) concentration was registered simultaneously at 2 to several heights above the mussel bed with sampling intervals from 10–60 min. The lowest sampling height always equaled 1-cm height above the mussel bed. Additional heights were up to 70 cm above the bed, depending on the study location. Sampling heights and intervals have been specified for each field-study day on the prepared figures of chl a contours. The water samples (50 mL) were taken manually by means of syringes attached to silicone pipes with endings through small holes in a rigid plastic pipe fixed in the bottom. Before sampling, the tubes were emptied of the "old" water (water from the prior sampling) to prevent mixing of new with old water. The water samples were immediately filtered on a GF/C filter (pore size = 1.2 μm) followed by 20 h of chl a extraction in 10 mL 96% ethanol. The fluorescence of the supernatant was measured on a fluorometer (Turner, model 450) and the fluorescence values were converted into concentration of chl a by means of a regression function determined for each day of study. The measured chlorophyll a concentrations represent time-averages over 5–6 min (= the water-sampling time).

In each field study a group of undisturbed mussels (from 4–10 individuals) was photographed every 5 min by means of a time-lapse video camera (Sony TRV 25) installed in a housing (Ikelite) fixed on a heavy tripod. The pictures (resolution: 480×640 pixels 2) were analyzed for the valve gapes (i.e., the distance between the valves) of the mussels. For each particular mussel the valve gapes were standardized to the observed maximal valve gape of the mussel during the particular time-series. Hence, a valve-opening degree of 100% represents the maximal valve gape of the mussel. An uncertainty test making repeated measurements of the same distance revealed a measuring uncertainty for the valve gape analysis between 6% and 28% (the larger the distance measured, the less the uncertainty). Consequently, the results from the deeper part of the mussel bed, where the mussels were registered with less camera zoom, are expected to be more uncertain. Minor uncertainties in valve gapes are caused by smaller variations in the orientations of the mussels to the camera during recording.

Prior to the field observations, mussel density (D , ind. m^{-2}), mean shell length (L , mm), and area-specific population-filtration rate of the mussel bed (F_{pop} , $m^3 m^{-2} d^{-1}$) were determined and the patchy distribution of mussels was mapped using Global Positioning System (GPS). F_{pop} was estimated as: $F_{pop} = \sum F_{ind}/A$, where F_{ind} ($l h^{-1}$) = $0.0012L^{2.14}$ (Kiorboe & Møhlenberg 1981, corrected by Riisgaard 2001a) and A = the area investigated for mussels. Knowing the water depth (H , m) and assuming complete mixing of the water column, the half-life time of phytoplankton above the mussel bed was calculated as: $t_{1/2} = H \times \ln 2 / F_{pop}$.

The test statistics (significance level $\alpha = 0.05$) have been calculated in Microsoft Excel 2003 and compared with critical values from Zar (1999).

RESULTS

Laboratory Studies

Figure 2 shows an example of valve opening response (during the first 15 min) to an addition of algal cells to a group of starved mussels, and further, after a period with a maintained algal concentration between 1000 and 5000 cells mL^{-1} to ensure maximum valve gape, the figure shows the closing response to a decreasing algal cell concentration. Figure 3 shows similar valve closing responses caused by low algal concentrations in two experiments. In the first experiment (Fig. 3A), a group of mussels was initially fed for 6 days before recording of the valve-gape closing response and then subsequently starved during the following 20 days. Initially the mean valve gape decreased nearly linearly, but the closing response was faster in fed than in starved mussels. In the second experiment (Fig. 3B), the group of mussels was starving during the whole experimental period. Both after 6 and 21 days of starvation the mean valve gape initially decreased nearly linearly, but the closing response was slower in the mussels starved for 21 days.

Figure 4 shows the opening response of mussels to addition of algal cells at time zero. It is seen that the opening time depends on the preceding feeding conditions in such a way that starved mussels seem to have a longer opening time than previously fed mussels. The opening response time for mussels fed daily with algal cells is shown in Figure 5. During the algal exposure period of 6 days, the duration of the opening response is decreasing, whereas, after a subsequent starvation period of 20 days, the opening response time had increased. The observed valve gape responses to presence/absence of algal cells in the ambient water shows that the

Figure 2. *Mytilus edulis*. (A) Exponential decrease in algal cell concentration after repeated additions of algal suspension to a well-mixed aquarium with actively grazing mussels (Group #2A). Slope of regression lines represent filtration rates. (B) Mean valve gape of the mussels. Opening response (0–16 min), constant filtration rate and maximal valve gape (16–178 min), closing response (178–315 min).

valve opening/closure responses are strongly influenced by the preceding feeding conditions.

Valve-closing response were also studied in steady-state feeding experiments and Figure 6 shows that the duration of the closing response initially declined with algal exposure time to become near constant in the remaining period, whereas on the other way round, the duration of the closing response was increasing during the subsequent starvation period. Figure 7 shows a similar closing response, although less pronounced. The closing response is slowly decreasing with the algal exposure time from Day 1 to Day 18 to be constantly low (about 10 min) during the rest of the feeding period. In the subsequent starvation period (from Day 29 to Day 50), the duration of the closing response increased apparently linearly as a function of time at a rate of about 10 min d⁻¹. The duration of the opening response (defined as the time from readdition of algal cells after a short period of valve closure caused by stoppage of the dosing pump until the mean valve gape had increased to maximum) is shown on Figure 8. It is seen that during the period in which the mussels were exposed to a constant steady-state algal cell concentration (from Day 1 to Day 38), the duration of the opening response was about 90 min, but in the subsequent starvation period (from Day 39 to Day 68) the opening-response time decreased to about 20 min. The previous observations indicate that the period during which mussels may “learn” or “forget” to respond to the presence/absence of algal cells can last for weeks.

Mussels that were maximally open and actively filtering at a low steady-state concentration of about 700 *Rhodomonas* sp. cells mL⁻¹ responded to a slight reduction in the algal concentration by a nearly immediate reduction in valve gape (Fig. 9). From this observation it can be concluded that the critical algal concentration below which the mussels close their valves is only slightly lower than 700 *Rhodomonas* sp. cells mL⁻¹, or 0.9 µg chl *a* L⁻¹.

Field Studies

The density, mean shell length and calculated area-specific population-filtration rate (F_{pop}) of the mussel bed are shown in Figure 1. F_{pop} ranged between 38 and 166 m³ m⁻² d⁻¹, with a local maximum of 255 m³ m⁻² d⁻¹ (not shown). Assuming a maximal water depth of 1 m and complete water mixing, the calculated half-life time of phytoplankton above the mussel bed is between 6 and 26 min. Because complete water mixing may never be attained in the benthic boundary layer, the actual half-life of phytoplankton in the near-bed water is likely to be even shorter. Hence, a considerable depletion in near-bed chl *a* concentration was expected on the mussel bed around tidal slacks.

The time-series of water depth, current speed (averaged over 5–10 min), chl *a* concentration, and valve-opening degrees of the mussels from the 10 field-study days are depicted in Figure 10. The water depth and current speed both followed the semidiurnal tide. The tidal range was up to about 0.4 m and the current speed ranged between tidal maxima of up to 0.4 m s⁻¹ at 20 cm above the mussel bed and zero when the tide changed between in- and out-going flow. In general, the measured variables showed tidal variation. The transition from strong to zero tidal flow was recorded on field-study days #1 to #3 (Fig. 10). It is seen that the mussels were wide open in the initial phase of strong tidal flow with near-bed chl *a* concentrations above 1 µg L⁻¹, whereas around tidal slack, where the near-bed phytoplankton biomass was grazed below about 1 µg chl *a* L⁻¹, the mussels reduced their valve gapes. A time lag in the response to low phytoplankton concentrations may be expected, which may explain why (e.g., the mussels in the first 15–30 min of field-study day #3) are fully open even though the chl *a* concentration is extremely low. Likewise, maintained maximal valve-opening degrees are observed during strong tidal flow

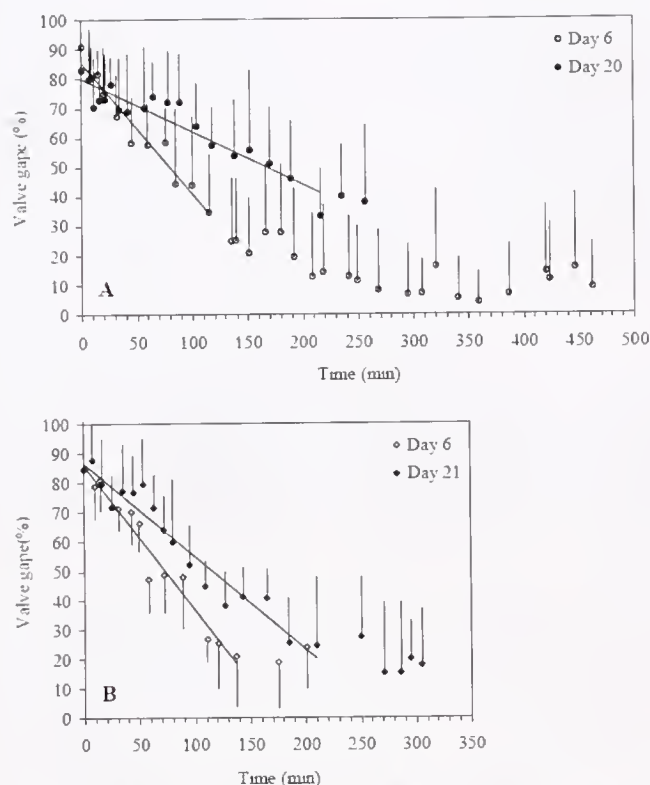

Figure 3. *Mytilus edulis*. Valve-gape closing response in short-term algal exposure experiments in which 0 min is the time when the decreasing algal concentration in the aquarium with filtering mussels passed $1,000 \text{ Rhodomonas sp. cells mL}^{-1}$. (A) Reduction of the mean valve gape (VG, % \pm SD) as a function of time (t , min) in Group #2A on Day 6 (\circ) and Day 20 (\bullet). The initial reduction in valve gape could be expressed by the inserted regression lines: $VG = -0.443t + 85.4$ ($r^2 = 0.946$) and $VG = -0.179t + 80.0$ ($r^2 = 0.880$) for Day 6 and Day 20 respectively. (B) The initial reduction of valve gape recorded in Group #2B on Day 6 (\diamond) and Day 21 (\blacklozenge) could be expressed by the inserted regression lines as: $VG = -0.505t + 86.6$ ($r^2 = 0.949$) and $VG = -0.316t + 86.7$ ($r^2 = 0.939$) for Day 6 and Day 21 respectively.

on field-study day #4 for most of the mussels. During field-study days #5 and #6 it was observed, as the tidal flow reincreased after tidal slack, that the near-bed chl a concentration increased above $1 \mu\text{g L}^{-1}$, whereas at the same time the mussels reincreased their valve-opening degrees to maximum. The same pattern with temporary reductions in mussel valve gapes during tidal slack appears from the field-study days #7, #8, and partly field-study day #9, carried out on the deeper part of the mussel bed (Fig. 1, Study site 2). More scatter in the depicted valve-opening degrees is expected from these 3 field-study days because of a higher uncertainty in the valve-gape analysis. However, on field-study day #9 the high degree of scatter in valve gapes and resultant low mean valve-opening degree seem to be markedly pronounced (even at high tidal flow rates) coincident with a constant exposure to extremely low near-bed chl a concentrations (below $1 \mu\text{g L}^{-1}$). Hence, short-term individual variability in valve valve-gape may be an indicator of shorter starvation periods. The extremely low chl a concentrations registered on field-study day #9 may be explained partly by incoming low chl a concentrations from the seaside and/or partly by limited replenishment of phytoplankton above the mussel bed because of a small tidal range this day. To this end, the results from field-study day #10 show an atypically valve-gape behavior. In

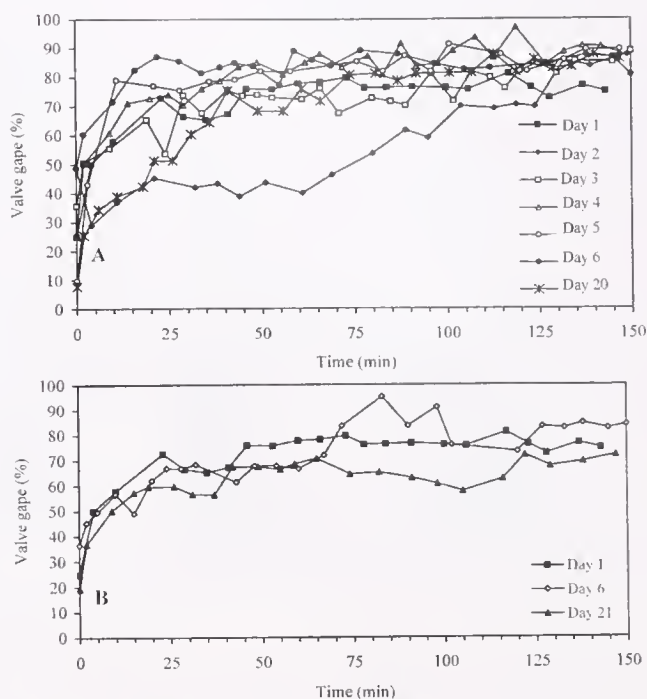

Figure 4. *Mytilus edulis*. Opening response of mussels in short-term experiments. (A) Mean valve gape as a function of time after algal addition to aquarium at time zero for mussels in Group #1 and Group #2A on Day 1, 2, 3, 4, 5, 6, and Day 20. (B) Mean valve gape for mussels in Group #1 and Group #2B on Day 1, 6, and Day 21 after addition of algal cells at time zero.

particular, for one of the mussels a prolonged (150 min) valve-gape reduction phase is initiated at a high tidal flow rate and chl a concentrations well above $1.5 \mu\text{g L}^{-1}$. It is not clear whether the chl a concentration of the inhalant water of the particular mussel has been lower than the registered one at 1 cm above the mussel bed.

Figure 11 shows the ratio of near-bed to surface chl a concentration (C_b/C_s) versus current speed (pooled raw data and data-fit). An analysis of variance (F -test, Zar 1999) showed a significant ($P < 0.0005$; $r^2 = 0.25$) data-fit to the following asymptotic regres-

Figure 5. *Mytilus edulis*. Opening response for mussels (Group #2A) in short-term experiment. The duration of the opening response, defined as the time from start of experiment until mean valve gape was 80% of the maximum registered. When the mussels were exposed to algal cells the opening response (DO , min) was linearly decreasing with time (t , d). The inserted regression line for Day 1 to Day 6 (+algae): $DO = -27.8t + 178.8$ ($r^2 = 0.911$); line for Day 6 to Day 20 (-algae): $OP = 4.14t - 8.86$.

Figure 6. *Mytilus edulis*. Valve gape closing response for mussels (Group #3) in long-term experiments. The closing response as a function of time during which the mussels were first exposed to algae (Day 1 to Day 38) followed by a period without algae (Day 38 to Day 68). Trends have been expressed by inserted regression lines.

sion model: $C_p/C_s = 1.794 - 1.147e^{-0.00104U/F_{pop}}$, where U ($m s^{-1}$) = the current speed and F_{pop} (the area-specific population-filtration rate of the mussel bed) = $1.16 \times 10^{-3} m^3 m^{-2} s^{-1}$. Hence, the vertical chl *a* gradient above the mussel bed became steeper as the current speed decreased.

Figure 12 (left) shows the means of the time-averaged (1 h intervals were used to approach independence between pooled valve-gape data) valve-opening degrees in various tidal flow phases. On the basis of a nonparametric analysis of variance by ranks (Kruskal-Wallis test; Zar 1999) it is found that the mean valve-opening degrees were different between flow phases ($P < 0.0005$). A subsequent nonparametric multiple comparison test using rank sums (Dunn test; Zar, 1999) shows that the mean valve-opening degrees observed in the flow phases $t = -3, -2, -1$, and 2 were not significantly different from each other, but the mean valve-opening degrees in the flow phases $t = -3, -1$, and 2 were significantly ($0.005 < P < 0.01$) different from the reduced ones observed around tidal slack at $t = 0$ and $t = 1$. The mean valve-opening degrees have also been plotted versus the corresponding mean time-averaged near-bed chl *a* concentrations in Figure 12 (right). It is seen that the mean near-bed chl *a* concentrations were generally low ($< 1.6 \mu g L^{-1}$) and that reduced valve-opening degrees associated with chl *a* concentrations below $1.0 \mu g L^{-1}$. Table 2 shows a calculated "grazing index," chl *a*_b/chl *a*_a, where the underscores "b" and "a" refer to the time just before and right after a valve-gape opening-closing response, respectively. The index is significantly lower ($0.005 < P < 0.01$) for the valve-closing phase

Figure 7. *Mytilus edulis*. Valve closing response for mussels (Group #4) in long-term experiments. The closing response as a function of time during which the mussels were first exposed to algae (Day 1 to Day 28) followed by a period without algae (Day 28 to Day 50). Trends have been expressed by inserted regression lines.

Figure 8. *Mytilus edulis*. Valve gape opening response for mussels (Group #3) in long-term experiment. The opening response (DO , min) as a function of time (t , d) during which the mussels were first exposed to algae (Day 1 to Day 38) followed by a period without algae (Day 38 to Day 68). For the period without algae, the decreasing opening response can be described by the equation: $DO = 10^6 t^{-2.656}$ ($r^2 = 0.922$).

compared with the valve-opening phase, which shows that the closing and opening phase occurred simultaneously with a decrease (grazing index < 1) and increase (grazing index > 1) in near-bed chl *a* concentration, respectively. The proposed causal relation between near-bed phytoplankton biomass (chl *a*) and mussel valve gape was investigated further in a shallow tidal lagoon close to Kerteminde Fjord. Here, 4 mussels settled on the bottom and 2 mussels settled on a stone 16 cm above the bottom, respectively, were video-registered simultaneously. The current speed was below the detection level ($= 0.05 cm s^{-1}$) of the current propeller, but changes in the tidal flow was estimated visually by following small particles in the flow. The results have been shown in Figure 13. It is seen that the benthic concentration-boundary layer increased in thickness during the recording interval, along with a decrease in tidal flow rate (not shown). As the near-bottom chl *a* concentration became below $0.8 \mu g L^{-1}$, the 4 mussels on the bottom reduced their valve gapes, whereas the 2 mussels on the stone higher up in the concentration boundary layer remained fully open.

Finally, the distributions of the valve-opening and closing times (taken from reduction of the valve-opening degree from 100% to 50%, and opening from 50% to 100%, respectively) have been

Figure 9. *Mytilus edulis*. Identification of critical algal concentration for stimulation of maximum valve gape in a group of mussels. At the initial steady-state algal concentration of about 700 *Rhodomonas* sp. cells mL^{-1} the mussels are maximally open, but reduction in algal concentration caused by temporary stoppage of algal dosing pump results in a closing response, that is followed by an opening response when the algal dosing pump is reactivated resulting soon after in a re-established steady-state where the mussels are again fully open.

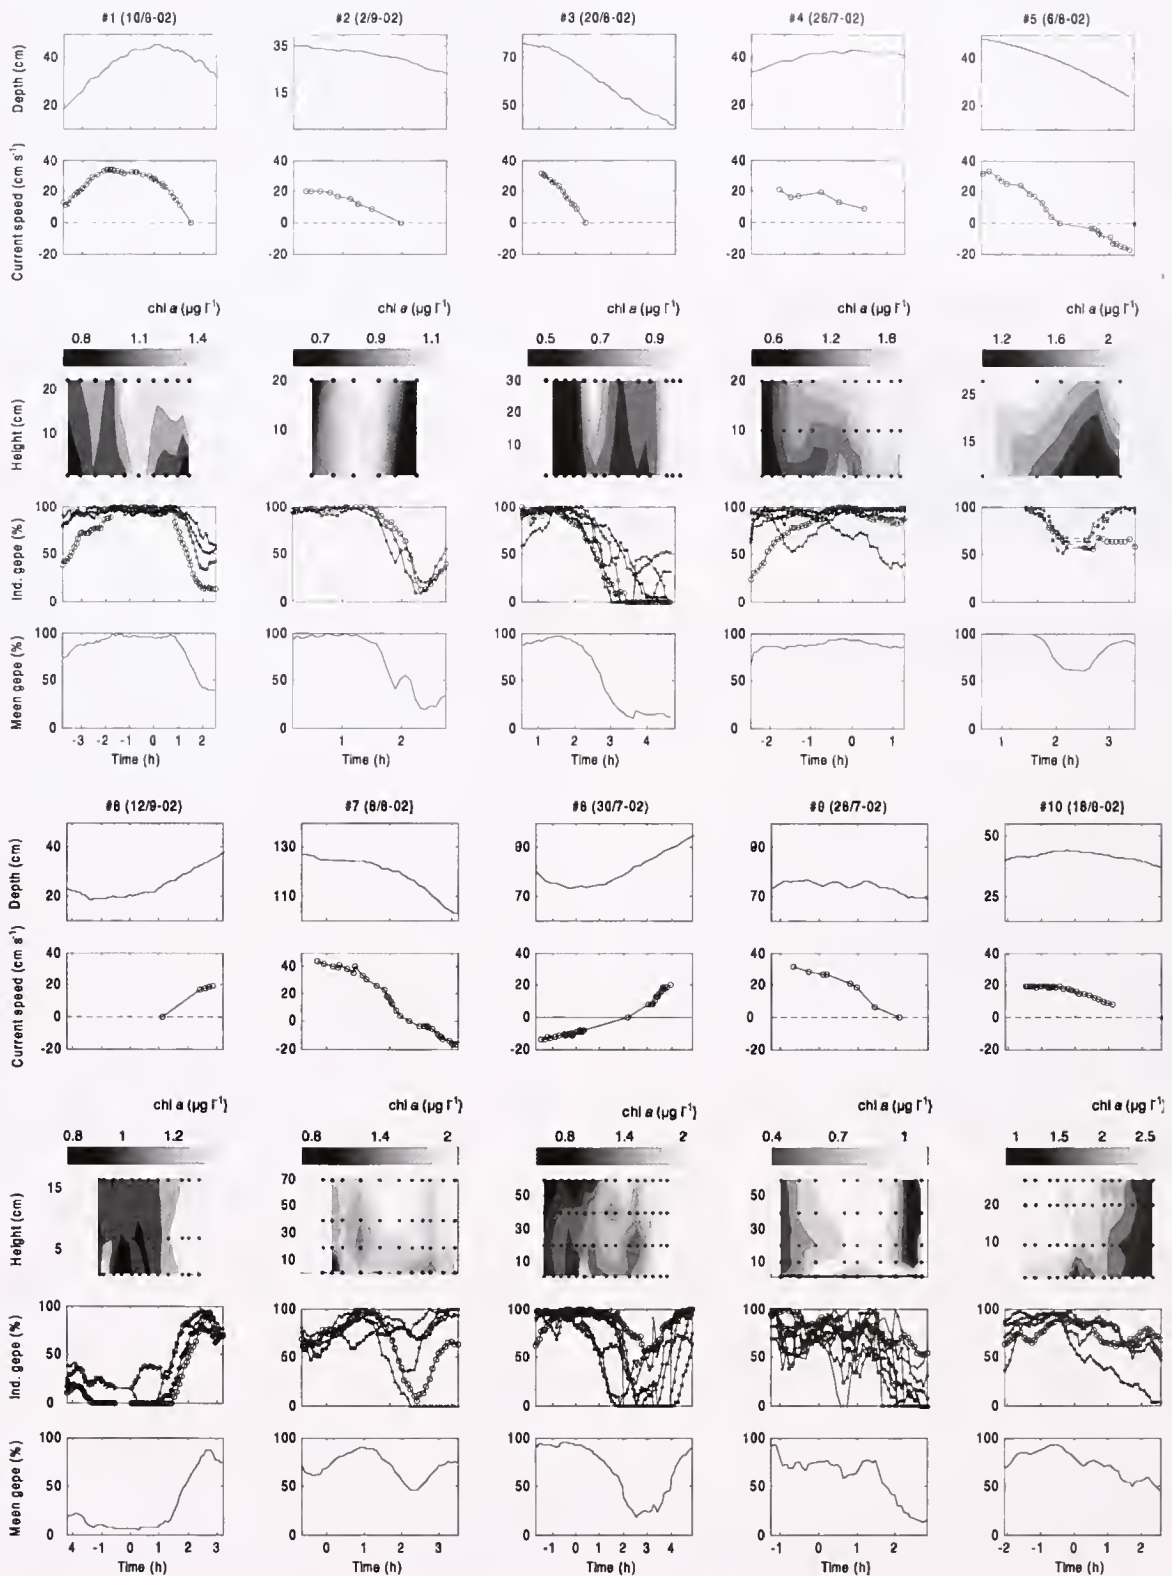

Figure 10. Field-study days #1 to #10 in Kerteminde Fjord: Top to bottom: Time-series of water depth above mussels, current speed, contours of chl *a* concentration ($\mu\text{g L}^{-1}$) above the mussel bed (sampling time and heights above the mussel bed marked with dots), individual percentage valve-opening degree, and mean percentage valve-opening degree of the mussels. Current speeds above and below zero indicate in- and outgoing tidal flow, respectively. Height 1 cm in the chl *a* contours represents 1 cm above the mussels.

Figure 11. Pooled data of the depletion index (C_p/C_s) versus tidal current speed. Least squares asymptotic fit of data ($r^2 = 0.25$; $P < 0.0005$): $C_p/C_s = 1.794 - 1.147e^{-0.00104U/F_{pop}}$, where U ($m\ s^{-1}$) = the current speed, and F_{pop} (the area-specific population-filtration rate of the mussel bed) $= 1.16 \times 10^{-3}\ m^3\ m^{-2}\ s^{-1}$ ($= 100\ m^3\ m^{-2}\ d^{-1}$)

shown in Figure 14. Table 2 shows that the mean duration of the mussel closure phase were almost of same duration: 50 and 59 min, respectively.

DISCUSSION

Laboratory Studies

In a recent work Riisgård et al. (2003) studied the valve opening-closing phenomenon and response times in three species of filter-feeding bivalves (*Cardium edule*, *Mytilus edulis*, *Mya arenaria*) in the presence and absence of algal cells in controlled laboratory experiments. Opening state and correlated filtration rate at varying or maintained levels of algal concentration was studied in filtration rate experiments combined with video observation. When initially unfed bivalves were offered algal cells, the animals soon opened their siphons/valves simultaneously with a pronounced increase of the filtration rate. On the other hand, when open and actively filtering bivalves experienced decreasing algal

concentrations below a certain level, this lead within a few hours to a reduced opening state and cessation of filtration activity. However, a considerably shorter valve-closure response time of only 15 min was recorded by Riisgård & Randlov (1981). The short response time may be caused by the experimental conditions because the valve-gape observations were made as part of a long term (47 d) feeding experiment imitating realistic, natural food concentrations. This suggestion is in agreement with the present observations.

This study shows that the duration of the well-known valve-gape response of mussels to the presence or absence of algal cells in the ambient water (Riisgård et al. 2003) is strongly influenced both by the preceding feeding conditions and the length of starvation. The period during which mussels may "learn" or "forget" to respond to the presence or absence of algal cells has been found to last for weeks in mussels kept in the laboratory. This knowledge is relevant for a correct understanding of the frequently used term "acclimation" (e.g., acclimation of experimental mussels to different laboratory conditions) such as changes in temperature, salinity or feeding conditions in experimental set-ups or storage tanks with or without through-flowing seawater, see also Kittner & Riisgård (2005). Many parameters (e.g., oxygen uptake rate, filtration rate, elimination- and uptake rates of pollutants) measured in different studies using mussels as experimental animals are strongly dependent on the valve-opening degree, and thus—although indirectly—the preceding feeding conditions or length of starvation after being collected in the field. Newly collected mussels may react very differently to experimental conditions compared with long-term laboratory "acclimated" mussels.

Valve closure and cessation of filter feeding in mussels at algal concentrations below a certain trigger level has been designated "lower trigger-level cessation" by Riisgård (2001b). In the present work, this critical algal concentration has been determined to be about $0.9\ \mu g\ chl\ a\ L^{-1}$ in quite good agreement with a suggested lower trigger-level of about $0.5\ \mu g\ chl\ a\ L^{-1}$ (Clausen & Riisgård 1996, Dolmer 2000a, 2000b). The valve-closing phenomenon, and subsequent reduction of the metabolism (Jørgensen et al. 1986), seems to represent an adaptation to filter feeding in extremely meager situations as discussed by Riisgård (2001b). From the present laboratory findings it seems likely that the valve opening/

Mytilus edulis. Mean duration \pm SD of valve gape closing phase (taken as the duration from valve-opening degree 100% to 50%) and opening phase (taken as duration from valve opening degree 50% to 100%). Mean grazing index: $(\text{chl } a_p/\text{chl } a_a)_{\text{mean}}$, where $\text{chl } a_p$ = the near-bed chlorophyll *a* concentration right before initiation of the valve-gape response and $\text{chl } a_a$ = the near-bed concentration right after initiation of the valve-gape response. *N* = sample size.

	Closure Phase	Opening Phase
Mean duration \pm SD (min)	59 \pm 22 (<i>N</i> _{mussel} = 26)	50 \pm 19 (<i>N</i> _{mussel} = 13)
Mean (chl <i>a_p</i> /chl <i>a_a</i>) \pm SD	0.8 \pm 0.2 (<i>N</i> _{chl <i>a</i>} = 6)	1.2 \pm 0.1 (<i>N</i> _{chl <i>a</i>} = 4)

closing-response times in the field may be considerably faster than usually observed in the laboratory, a suggestion that has been confirmed by the present field studies.

Field Studies

Filter-feeding mussels are important sinks for phytoplankton in shallow fjords and coastal waters. In such places dense mussel beds with area-specific population filtration rates of 100–200 m³ m⁻² d⁻¹ may exert a considerable grazing impact (Jørgensen 1984, 1990), as also confirmed by the present work (Fig. 1). The phytoplankton biomass in areas with mussel beds may be significantly reduced, and a pronounced near-bottom concentration-boundary layer may develop (Fréchette et al. 1989, Prins et al. 1998, Norén et al. 1999, Dolmer, 2000a, Tweddle et al. 2005). The steepness of horizontal and vertical gradients in the phytoplankton biomass in such a boundary layer is determined by current speed and turbulent mixing of the ambient water (van Duren 2005, Lassen et al. 2006). Consequently, mussels in dense beds may experience a dynamic nutritional environment as also demonstrated in the present work. The results shown in Figure 11 agree with earlier findings that mussels within a mussel bed become increasingly limited in their supply of phytoplankton at decreasing current speeds caused by steeper horizontal and vertical phytoplankton gradients above the mussel bed (Fréchette et al. 1989, Dade 1993, Butman et al. 1994, van Duren et al. 2005, Lassen et al. 2006, Tweddle et al. 2005). The tidal flow rate clearly had an effect on the valve-gape behavior of the mussels (Fig. 11), but the present study suggests this effect to be an indirect one, because the mussels (located between dense macro-algae, *Fucus* sp.) were never exposed to such high current speeds reported to affect the valve gape of mussels (see e.g., Newell et al. 2001). As pointed out by Yu & Culver (1999), local zones of depleted water may be found inside dense mussel beds and this phenomenon is likely to have caused the observed “atypical” behavior of the mussels on field-study day #10 (Fig. 10).

Prevailing phytoplankton concentrations in noneutrophicated waters usually lie between 1 and 5 μg chl *a* L⁻¹, and in this concentration interval the blue mussel is wide open and filtering at maximum rate (Riisgård 2001a, Riisgård et al. 2003). However the phytoplankton biomass in the near-bottom concentration boundary layer is often substantially lower. Thus, Dolmer (2000a) measured the vertical distribution of phytoplankton above *Mytilus edulis* beds in Limfjorden, Denmark. In one case, the chl *a* concentration measured 2 m above the mussel bed (3.2 μg L⁻¹) declined towards the bottom to about 0.3 μg L⁻¹, which is less than the threshold

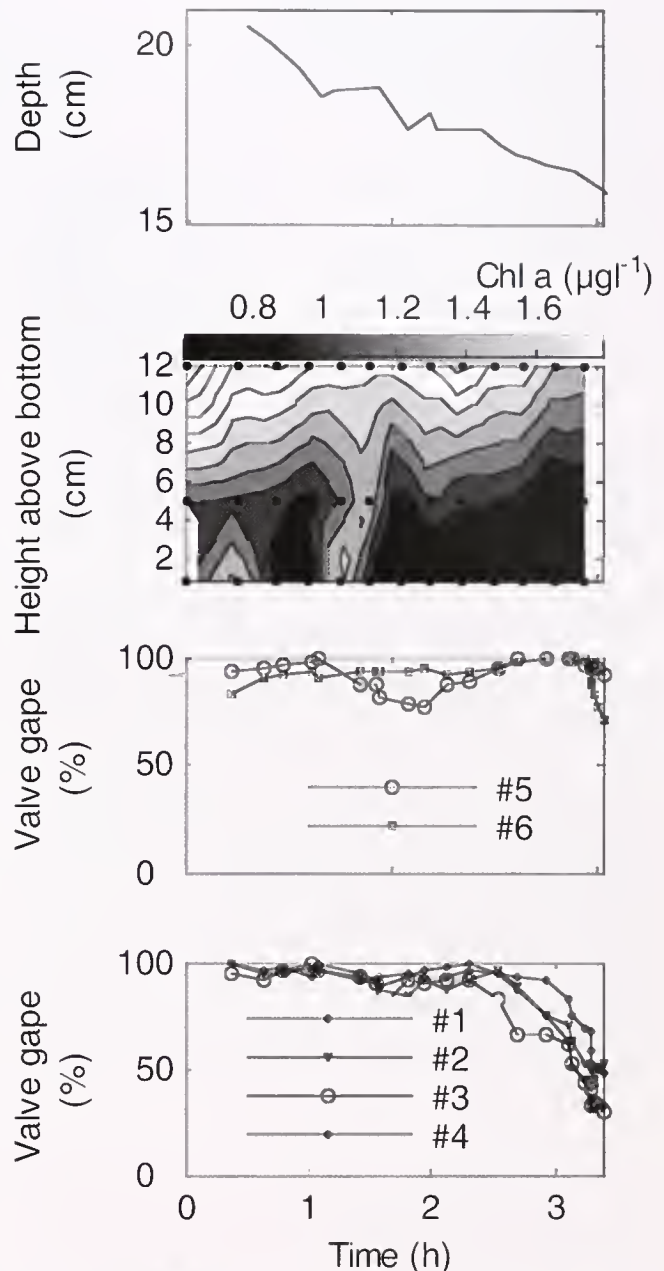

Figure 13. Field study in shallow lagoon close to Kerteminde Fjord. Time-series of water depth, contours of chl *a* concentration (μg L⁻¹) (sampling time and heights above the mussel bed marked with dots), individual percentage valve-opening degrees of mussel #5 & #6 placed on a stone 15 cm above the bottom, individual percentage valve-opening degrees of mussel #1 to #4 placed on the bottom. Height zero in the chl *a* contours represents 1 cm above the bottom.

value (0.7–1.0 μg L⁻¹) below which the blue mussel closes its valves (Clausen & Riisgård 1996, Dolmer 2000a; b, Newell et al. 2001, Kittner & Riisgård 2005). As stated by Riisgård (2001b) the valve-closing phenomenon, which has also been clearly demonstrated in the present work, represents a physiological adaptation to filter feeding in extremely meager situations, when a reduced valve gape reduces the metabolism of the mussel (Jørgensen et al. 1986).

Tidally induced variation in bivalve filtration activity (valve gape and/or siphon opening degree) has earlier been observed in

Figure 14. Percentage distributions of valve-gape opening (squares) and closing (triangles) times, taken as the duration from valve-opening degree 50% to 100% and 100% to 50%, respectively.

situ in *Mya arenaria* (Roegner 1998, Thorin et al. 1998), *Mytilus edulis* (Newell et al. 1998, 2005), and *Venerupis corrugatus* (Stenton-Dozey & Brown 1992). Newell et al. (1998) registered coincidence between reduced valve gapes in *M. edulis* and low particle concentrations in during the tidal period, but the observed responses in valve gape/siphon opening were not directly correlated to tidally driven variation in phytoplankton biomass in the near-bottom water. Recently, Newell et al. (2005) registered two peaks in exhalant opening diameter of *M. edulis* in a dense bed: a peak when new water with food particles was brought in by the tide, and a peak during ebb, coincident with a high settling flux of marine snow. In the remaining tidal period the mussels had reduced valve gapes. The present study shows that the valve gape of mussels is maximum during tidal phases with sufficiently high flow and near-bed chl *a* concentrations above roughly $1 \mu\text{g L}^{-1}$, but at slower flow rates and chl *a* concentrations $<1 \mu\text{g L}^{-1}$ the mussels reduce their valve gape. The present observations indicate

that the mussel *in situ* valve gape opening-closing response to variation in phytoplankton biomass is short (50 min) compared with the response times in unfed mussels in the laboratory (up to 180 min) (Riisgård et al. 2003), but compare well with fed mussels in the present laboratory studies and with results from a field-study conducted by Newell et al. (1998). It can be read from Figure 6 in Newell et al. (1998) that the closure response of *M. edulis* in Mud Cove (Maine, USA) was about 60 min, whereas the subsequent opening phase was slightly shorter (about 40 min).

CONCLUSION

Laboratory studies of valve-gape response of mussels to presence or absence of algal cell have demonstrated that valve opening and closing response times are strongly influenced by the preceding feeding conditions. The period during which mussels may "learn" or "forget" to respond to the presence or absence of algal cells can last for weeks in the laboratory. Field studies have revealed that phytoplankton concentrations higher than about $1 \mu\text{g chl } a \text{ L}^{-1}$ stimulate the mussels to keep their valves wide open, whereas lower near-bed concentrations cause valve closure, or reduced valve gape. The *in situ* valve opening and closing times in response to variation in near-bed chl *a* concentration are considerably faster than in unfed mussels in the laboratory. This knowledge is essential for making allowance for deviation from natural response times in mussels kept in the laboratory previous to experimental physiological studies. Further, the opening/closing response times to presence/absence of phytoplankton may influence the actual grazing impact of mussels, and therefore, awareness of response times may be of importance for future modeling because of hysteresis that can mask the connection between filter-feeding activity and the concentration of phytoplankton.

GROWTH, PRODUCTION AND ECONOMIC EVALUATION OF EARTHEN PONDS FOR MONOCULTURE AND POLYCULTURE OF JUVENILES SPOTTED BABYLON (*BABYLONIA AREOLATA*) TO MARKETABLE SIZES USING LARGE-SCALE OPERATION

S. KRITSANAPUNTU,¹ N. CHAITANAWISUTI,^{2*} W. SANTHAWEESUK² AND Y. NATSUKARI³

¹Faculty of Technology and Management, Prince of Songkla University, Suratani, Thailand; ²Aquatic Resources Research Institute, Chulalongkorn University, Bangkok, Thailand 10330; ³Faculty of Fisheries, Nagasaki University, 1-14 Bunkyo-Machi, Nagasaki, 852 Japan

ABSTRACT The study was conducted to determine the feasibility for growing-out of the spotted babylon juveniles (*Babylonia areolata*) to marketable sizes with the large-scale operation of 20.0 × 20.0 × 1.5 m earthen ponds at Petchaburi province, Thailand. The production and economic analysis for monoculture of spotted Babylon were compared with the polyculture with sea bass (*Lates calcarifer*). Each pond was stocked with juveniles of 0.3 g initial weight at a density of 200 snails m⁻². This study provides good results in growth and production of spotted babylon in earthen ponds. The average growth rates in body weight were 0.67 and 0.51 g mo⁻¹ for snails held in the monoculture and polyculture with sea bass, respectively. At the end of the experiment, total yield of spotted babylon held in the monoculture and polyculture with sea bass was 10,520 and 10,450 kg ha⁻¹, respectively. Based on farm data, stocking data and harvest data used in this study, total cost per production cycle of the monoculture and polyculture with sea bass were \$19,184 and \$23,245, respectively. The cost of producing spotted babylon marketable sizes in this grow-out farm design was \$5.69 per kg and \$6.95 per kg for the monoculture and polyculture trials, respectively. At a farm gate price in 2003 of \$9.00 per kg resulted in a net return of \$11,124 and \$14,691 for the monoculture and polyculture with sea bass, respectively. The present study indicated the technically feasible, and economically attractive for monoculture and polyculture of *B. areolata* to marketable sizes in earthen ponds.

KEY WORDS: *Babylonia areolata*, *Lates calcarifer*, monoculture, polyculture, earthen ponds, production, economic analysis

INTRODUCTION

Recently, there has been considerable interest in the commercial culture of spotted babylon, *Babylonia areolata*, in Thailand resulting from a growing demand and an expanding domestic market of seafood, and a catastrophic decline in natural spotted babylon populations in the Gulf of Thailand. From an aquaculture point of view, the spotted babylon had many biological attributes, production and market characteristics necessary for a profitable aquaculture venture and it was considered a promising new candidate of aquaculture species for the land-based aquaculture industry in Thailand (Chaitanawisuti & Kritsanapuntu 1999). At present, the successful culture of spotted babylon juveniles to marketable sizes was operated in large-scale production using the flow-through seawater system in concrete/canvas ponds. However, this culture technique had many considerations in disadvantages of the culture purposes. Basically, it needed the high investment of pond construction, buildings and facilities, large area for pond construction, and operational costs, but the production and low economic returns is not high enough for commercial operations (Chaitanawisuti et al. 2002a, 2002b). Because many marine shrimp ponds (*Penaeus monodon*) have been abandoned or rested because of diseases, poor management and environmental degradation for a long time in Thailand, this study was then focused on the potential and feasibility for a pilot growing-out of the spotted babylon juveniles to marketable sizes in earthen ponds. This study may provide an opportunity to develop a sustainable aquaculture system for growing out of spotted babylon juveniles to marketable sizes in earthen ponds and may result in the best use of many abandoned/rested shrimp ponds in coastal areas of Thailand. However, lack of economic data can be an important constraint to the

successful development of spotted babylon aquaculture operations. A financial investment analysis which tied biological, production, cost and market price variables has been used to make decisions about culture methods, feasibility and potential for commercial operation of this enterprise. However, polyculture techniques have been used to increase production of fish and shellfish in culture ponds. Several marine shellfish species have been shown in polycultures, augmenting harvests through wider use of available food and space, whereas minimizing the negative effects of species—specific competitions and exometabolites. In addition, the polyculture of shellfish with fish presented some possibility that could benefit the local aquaculture operation (Hunt et al. 1995). A lack of economic data can be an important constraint to the successful development of spotted babylon aquaculture operations. A financial investment analysis which tied biological, production, cost and market price variables has been used to make decisions about culture methods, and feasibility and potential for commercial operation of this enterprise. Thereafter, the land-based aquaculture operation for growing-out of spotted babylon in earthen ponds was developed for commercial purposes in Thailand. The objective of this study is to present the growth, production and economic consideration for monoculture of juvenile *B. areolata*, and their polyculture with sea bass, *L. calcarifer*, using large-scale production of earthen ponds.

METHODS

Pond Design and Construction

This study was conducted at the Research and Development Unit for Aquaculture of the spotted babylon, Aquatic Resources Research Institute, Chulalongkorn University, Petchaburi province, Thailand, during 2003 to 2004. A total farm area of 0.8 ha was comprised of 0.32 ha grow-out earthen ponds, 0.4 ha seawater

*Corresponding author. E-mail: nilnajc1@hotmail.com

reservoir and 0.08 ha accommodation and office. Eight 20.0×20.0 m earthen ponds and 1.5 m in depth were used for the polyculture trials. Ponds were arranged in a 4×4 array with common walls to reduce construction costs and pond wall was 1.5 m in height, 3.0 m in width at the base and 2.5 m in width at the top. Ponds bottom was covered with coarse sand of approximately 10–15 cm in thickness. Each grow-out pond was fenced by plastic net of 15.0 mm mesh size and 1.2 m in width, supported with bamboo frame for strengthening. The plastic net must be buried under sand about 6 cm in depth to limit movement of snails along pond bottom and pond wall, and ease for harvesting. Prior to the start of the grow-out, all ponds were dried for 2 wk, and filled with ambient, unfiltered natural seawater from a nearby canal to a depth of 70 cm. Water level in the ponds was maintained at 70 cm by adding seawater to replace water loss caused by seepage and evaporation. The grow-out ponds are supplied with ambient unfiltered, natural seawater from seawater intake system. The seawater system was powered by one 5.5-hp engine equipped with water pump of 12.5 cm in diameter of outlet pipe. The seawater intake consisted of a 12.5 cm in diameter PVC pipe manifold horizontally into the sea. Seawater is delivered to each pond through main unlined canal of 80-cm width and 30-cm depth, and 15.0-cm diameter PVC distribution pipes (inlet). The drainage pipe of 12.5 cm in diameter PVC pipe was used as an outlet. Two air blowers (2 Hp) were used to supply high volume of air for all grow-out ponds. PVC pipes of 2.54 cm in diameter were connected to the outlet of the air blower and extended to the pond dike of each pond. Four polyethylene pipes of 18 m long and 1.6 cm in diameter was connected to the PVC pipe and extended to the bottom of each pond. On the PE pipe, there were 10 holes of 1.5 mm in diameter, and the distance between adjacent holes was 2 m. The PE pipes were sustained at 10 cm off the pond bottom using bamboo sticks. An aerator was operating daily for 16–20 h except during feeding and resting of blower.

Monoculture and Polyculture Trials

Spotted babylon and sea bass juveniles were purchased from private hatchery. Individuals from the same cohort were sorted by size to minimize differences in shell length (maximum anterior-posterior distance) and prevent possible growth retardation of small babylon when cultured with larger individuals. The spotted babylon juveniles had an average shell length and body weight of 1.0 cm and 0.3 g, respectively, and 12.7 cm and 37.2 g for those of sea bass, respectively. Two treatments of monoculture and polyculture were designed as following:

Treatment 1: Monoculture of Spotted Babylon

Initial stocking density of spotted babylon juveniles was 200 individuals m^{-2} (80,000 snails per pond).

Treatment 2: Polyculture of Spotted Babylon with Sea Bass

Initial stocking density of spotted Babylon and sea bass juveniles were 200 individuals m^{-2} (80,000 snails per pond), and 5 fish m^{-2} (2,000 fish per pond), respectively.

Grow-out Operation

The feeding schedule was as follows: sea bass were fed to satiation with fresh trash fish twice daily in morning (09:00 h) and evening (17:00 h). Spotted babylon were fed with fresh trash fish at 15% to 20% of body weight once daily in morning (09:00 h) this

was done after stopping feeding of the sea bass. Feeding was monitored daily by means of baited traps. Food amounts were adjusted every 30 d after body weight measurement. Fifty percent of seawater was exchanged at 15 d interval and seawater was sampled before water exchange at 25 cm above pond bottom for analyses of seawater temperature, salinity, pH, alkalinity, nitrite-nitrogen and ammonia-nitrogen following standard methods as described by APHA et al., 1985. Dissolved oxygen was measured daily. No chemical or antibiotic agent was used throughout the entire experimental periods. Grading by size was not carried out in any pond throughout the growing-out period. For growth estimation, 50 baited traps were used to sample the spotted babylon in each pond at 30 d interval for measurement of body weight individually and counting the number of snails per kg. The spotted babylon juveniles were cultured until they reached the marketable size of 120–150 snails per kg^{-1} .

Economic Evaluation

The components of financial analysis were categorized according to initial investment, annual ownership costs and annual operating costs as follows:

Initial investment requirements for farm construction on monoculture of juvenile spotted babylon and polyculture with sea bass to marketable sizes in earthen ponds were evaluated. The investment requirements included land, construction of eight $20.0 \times 20.0 \times 1.5$ m grow-out earthen ponds, one 0.4 ha seawater reservoir, two seawater pumps and housing, two blowers and housing, four $3.0 \times 5.0 \times 0.7$ m canvas nursery tanks and housing, accommodation for labor and office and operating equipment and facilities.

Ownership costs per production cycle consisted of land, depreciation and interest on investment. These costs are fixed and incurred in the short run regardless of whether the facilities are in operation. Annual depreciation was estimated by the straight-line method, based on the expected useful life of each item of equipment. Assets are assumed to have no residual value for all items constituting facilities at the end of their useful life. Eight $20.0 \times 20.0 \times 1.5$ m grow-out earthen ponds and one 0.4 ha seawater reservoir were assumed to have useful life of 5 and 2 y, respectively. Housing and the blowers and seawater pumps were assigned a useful life of 2 y. The life expectancies of equipment ranged from 1–2 y. Interest rates for capital cost were based on 2003 bank loan rates (3.5% per year) for this type of business enterprise.

Operating costs per production cycle are incurred upon actual operation of the grow-out unit and include repairs and maintenance, labor, feed, utilities and interest on operating capital. Costs for purchasing and transportation of spotted babylon and sea bass juveniles are \$0.02 and 0.11 per juvenile, respectively. Spotted babylon and sea bass are fed fresh meat of trash fish at a cost of \$0.13 per 0.18/kg and feed conversion ratio was 2.2. The repairs and maintenance is estimated on the actual expenses for housing, earthen ponds, reservoirs, and operating equipment costs. Electricity is used for operating the various pumps and lighting units in the farm. The average charge was \$0.03 per kilowatt hour. Labor requirements were based on the particular needs for production cycle of the proposed farm. Two operators (full-time) were assigned for operation of the farm; the cost of one operator was \$125.0 per month. Operating equipment (fuel, storage containers, farm equipment, etc.), chemicals and lime was estimated based on

actual use of each item. Land is actual lease from private sector at a rate of \$625 per ha per year. Interest charges for operating capital are based on 2003 bank loan rates (3.5% per year) for this type of business.

Return Analysis

Net return and return on investment for grow-out production were computed at the selling price of spotted babylon market sizes at farm gate in 2003 ranging from \$8.8–9.3/kg. Gross return was computed from total yield multiplied by selling price. Net return was calculated from the gross return minus to the total amount cost per production cycle. (Rubino 1992, Fuller et al. 1992).

RESULTS

Growth and Production

Growth expressed as body weight and number of snail per kilogram of juvenile *B. areolata* for monoculture and polyculture with sea bass over a period of 7 mo was shown in Figure 1 and Figure 2. Growth of spotted babylon was not significantly higher in monoculture, compared with growth in polyculture with sea bass ($P < 0.05$). The average growth rates in body weight were 0.67 and 0.51 g mo⁻¹ for snails held in the monoculture and polyculture with sea bass, respectively. Mean (\pm SE) final body weights of spotted babylon held in the monoculture and polyculture with sea bass was 5.22 \pm 0.63 g, and 4.10 \pm 0.57 g, respectively. Mean (\pm SE) final shell lengths of snails held in the monoculture and polyculture with sea bass was 3.2 \pm 0.35 cm, and 3.6 \pm 0.75 cm, respectively. The snails can reach the sizes of 205 \pm 17.55 and 214 \pm 43.90 individuals kg⁻¹ for the monoculture, polyculture with sea bass, respectively. Feed conversion ratio (FCR) was 2.69 and 2.71 for snails held in the monoculture and polyculture with sea bass, respectively. Final survival of snails held in the monoculture was 84.94%, and 84.30% for those held in polyculture with sea bass, respectively. At the end of the experiment, the average total yield of spotted babylon in monoculture and polyculture with sea bass were 10.525 and 10.450 kg ha⁻¹, respectively. Size distribution of the spotted babylon in monoculture was consisted of 2 main size classes of 100–250 and <250 snails/kg with 90.81% and 9.19%, respectively. For Polyculture with sea bass, the snails consisted of 2 main size classes of 100–250 and <250 snails kg⁻¹ with 87.57% and 12.43%, respectively. For sea bass, the average final weight, final survival, FCR and total production were 300–1,200 g, 46.0%, 4.47 and 12,250 kg ha⁻¹, respectively.

Economic Evaluation

Farm data (total farm area, pond sizes and total pond area), stocking data (average initial weight, stocking density) and harvest data (duration of grow-out, average weight at harvest, final survival, feed conversion ratio and yield) are based on the actual data of pilot farm. Parameters used for the economic analysis for monoculture and polyculture of spotted Babylon with sea bass in a total farm area of 0.8 ha were summarized in Tables 1, 2, 3, 4, 5. Total investment requirement for construction of a total farm area of 0.8 ha was estimated to be \$4,837 for the monoculture and polyculture trials. Construction of grow-out ponds and seawater reservoirs was the largest cost component of the farm (35.14% of the total investment cost), followed by building of canvas nursery ponds, land, seawater pumps and blowers representing 12.92%, 10.34%, 10.34% and 10.34% of the total investment cost, respec-

Figure 1. (A) Growth in body weight of juvenile *B. areolata* held in monoculture and polyculture with sea bass in earthen pond. (B) Growth in sizes (number of snails per kg) of juvenile *B. areolata* held in monoculture and polyculture with sea bass in earthen pond.

tively (Table 2). Ownership cost per production cycle was estimated to be \$2,241 for the monoculture and polyculture trials. The major ownership cost items were depreciation, land and interest on investment accounting 76.22%, 22.31% and 1.47% of total ownership cost, respectively (Table 3). Operating costs per production cycle was estimated to be \$16,943 and \$21,004 for the monoculture and polyculture trials, respectively (Table 4). Total cost per production cycle for the monoculture of spotted babylon in a total farm area of 0.8 ha was \$19,184 and \$23,245 for the monoculture and polyculture trials, respectively (Table 5). The cost of producing spotted babylon marketable sizes in this grow-out farm design was \$5.69 per kg and \$6.95 per kg for the monoculture and polyculture trials, respectively. The enterprise budgets based on the price of spotted babylon at farm gate in 2003 of \$9.00 per kg

TABLE 1.

Parameters used for the economic analysis for the monoculture and polyculture trials of spotted babylon in a total farm area of 0.8 ha of earthen ponds.

Parameters	Monoculture	Polyculture
	Amount (\$)	Amount (\$)
A. Farm data		
Total farm area (ha)	0.8	0.8
Pond size (ha)	0.04	0.04
Total pond area (ha)	0.3	0.3
Total area of seawater reservoirs (ha)	0.4	0.4
B. Stocking data		
Average initial weight of spotted babylon (g)	0.3	0.3
Average initial weight of sea bass (g)		2.3
Stocking density of spotted babylon (no. m ⁻²)	200	200
Stocking density of sea bass (no. m ⁻²)		5
C. Harvest data (Spotted Babylon)		
Duration of grow-out (mo)	7	7
Average number of crops per year per pond	1.4	1.4
Average final weight (g)	5.22	4.10
Average final survival (%)	84.94	84.30
Feed conversion ratio (FCR)	2.69	2.71
Yield per production cycle (kg/ha)	10,520	10,450
Selling price at farm gate (\$/kg)	8.75–9.25	8.75–9.25
D. Harvest data (Sea bass)		
Duration of grow-out (mo)		6
Average number of crops per year per pond		2
Average final weight (g)		300–1,200
Average final survival (%)		46.00
Feed conversion ratio (FCR)		4.47
Yield per production cycle (kg/ha)		12,250
Selling price at farm gate (\$/kg)		1.89–2.25

resulted in net return of \$11,124 and \$14,691 for the monoculture and polyculture trials, respectively (Table 6).

DISCUSSION

In this study, the average monthly growth rate, FCR and final survival of spotted babylon for monoculture in earthen pond were 0.67 g mo⁻¹, 2.69, and 84.94%, respectively, and the average monthly growth rate, FCR and final survival of spotted babylon were 0.51 g mo⁻¹, 2.71, and 84.30% respectively for polyculture with sea bass. The snails can reach a marketable size with an average body weight of 9–10 g in a 7-mo period of culture. By contrast, Chaitanawisuti and Kritsanapuntu (1999) reported that average monthly growth rates of spotted babylon in flow through culture system in concrete/canvas tanks was 1.4 g mo⁻¹, FCR and final survival were 1.6% and 95.8%, respectively. Chaitanawisuti et al. (2001) reported polyculture of *B. areolata* and *L. calcarifer* in 3.0 × 4.5 × 0.5 m concrete ponds supplied with flow-through seawater system that the average growth, survival, FCR and total production were 1.17 g mo⁻¹, 96.0%, 1.34 and 29.0

TABLE 2.

Estimated investments requirements for the monoculture and polyculture trials of spotted babylon in a total farm area of 0.8 ha of earthen ponds.

Items	Amount (\$)	%
Land renting	500	10.34
Construction of eight 20.0 × 20.0 × 1.5 m grow-out earthen ponds and one 0.4 ha seawater reservoirs	1,700	35.14
Construction of accommodation and storage house	250	5.17
Construction of four 3.0 × 5.0 × 0.7 m canvass nursery ponds and housing	625	12.92
Water pumps and housing	500	10.34
Blowers and housing	500	10.34
Traps for sampling and harvesting	100	2.06

Miscellaneous	500	10.34
Total investment	4,837	100

kg, respectively. Growth of spotted babylon in earthen ponds was lower than those in concrete/canvas tank. The most concerned major issues for slow growth of spotted babylon in earthen ponds is the soil sanitization caused by pond seepage, salinity increases caused by water evaporation, salinity decrease caused by heavy rain falls, fast deterioration of total alkalinity, appropriate feeding strategy and invasions of snails (*Cerithium* sp.) as follows: (1) excessive food caused the degradation of water quality and decay of pond bottom; (2) food competition from various predators such as the tiger prawn naturally occur in earthen ponds (*Penaeus monodon*), swimming crabs (*Portunus pelagicus*), mud crab (*Scylla* sp), carp (*Oreochromis mossambica*); (3) deterioration of water quality, particularly total alkalinity which, caused slower feeding of spotted Babylon; (4) salinity decrease during rainy season, which caused slower feeding and obvious slow growth and (5)

mineral competition from a large number of snails (*Cerithium* sp.) that competed for minerals in the seawater, particularly calcium for shell formation, which resulted in shell abnormality and slow growth. In this study, production and economic analysis was performed for monoculture of juvenile *B. areolata* to marketable sizes using a large-scale production of earthen ponds in Thailand. The analysis was based on actual cost and production data from a pilot commercial-scale farm. A total farm area of 0.8 ha was comprised of 0.3 ha grow-out earthen ponds, 0.4 ha seawater reservoir and 0.08 ha accommodation and office.

The enterprise budgets of monoculture based on the price of spotted babylon at farm gate in 2003 of \$9.00/kg, net return of the monoculture and polyculture were \$11,124 and \$14,691, respec-

tively. This study presented a positive net return and a payback period of less than five years are often used as business investment criteria. In Thailand, living spotted babylon fetched the selling prices ranging from \$11.25–15.00/kg at seafood restaurants and \$8.75–9.25 per kg at a farm outlets. The basic consumption in this study (juvenile price of \$0.02 per juvenile, production feed price of \$0.2 per kg, stocking density of 200 snails m⁻², and selling price of \$9.0 per kg) indicated that the proposed eight 20.0 × 20.0 × 1.5 m grow-out earthen ponds operation is economically feasible under these conditions. The feasibility of producing spotted babylon marketable sizes in pilot commercial grow-out earthen pond operation should be continued to be examined. Although returns are small, production with 80% survival and selling price of \$9.0 per kg is economically feasible under the assumptions used. The results showed that total yield of monoculture (10,520 kg/ha) and polyculture with sea bass (10,450 kg/ha) was gradually different. For cost and returns analysis, total cost per production cycle of polyculture with sea bass (\$23,245) was 17.47% higher than that of monoculture (\$19,184) because of increasing costs of sea bass juveniles and feed, and the net return per production cycle of polyculture with sea bass (\$14,691) was 24.28% higher than the monoculture (\$11,124). Results of this work showed that juvenile spotted Babylon could be successfully grown to marketable size in earthen ponds for monoculture and polyculture systems.

This study has basically demonstrated that it is possible to culture the spotted Babylon in earthen ponds such as the abandoned/rested shrimp ponds by stocking acclimated spotted babylon juveniles to marketable sizes. Thus, monoculture and polyculture of spotted babylon is environmentally friendly and economically attractive with appropriate abandoned/rested shrimp farms, resulting in effective reuse of abandoned shrimp ponds, better economic returns and less environmental pollution. Furthermore, the polyculture of spotted babylon with sea bass or milkfish at relatively low stocking density may provide an opportunity to develop a sustainable aquaculture system to best use many abandoned/rested shrimp ponds in various coastal areas of Thailand. The results of this study provide preliminary evidence for the biological feasibility of culturing the spotted Babylon, *B. areolata*, in earthen ponds for monoculture and polyculture. However, application of

these results to commercial levels of production should be preceded by careful examination of other parameters that might be important, such as deterioration of water quality at high stocking densities. Further study should concentrate on pond design, management of seawater and pond bottom quality, feeding strategy and competition for food and habitat caused by natural occurrence of organisms, for the success of commercial grow-out operation of spotted babylon in earthen ponds.

ACKNOWLEDGMENTS

The authors thank the National Research Council of Thailand (NRCT), who provided funding for this research in fiscal year 2003 to 2004. The authors also express sincere thanks to Professor Dr. Yutaka Natsukari, Faculty of Fisheries, Nagasaki University, for his supervisors who were involved in the research and revision of this manuscript.

ABSTRACT Recent range extensions of the invasive rapa whelk *Rapana venosa*, biological data of the population and possible ecological impacts on the food webs of the Río de la Plata estuary are presented. A total of 41 rapa whelks and 21 egg capsules were collected between February 2004 and March 2006. Specimens were found all over the mixohaline waters of the estuary, with records off Montevideo, Samborombón Bay and off Punta Rasa. Specimens ranged between 28 and 120 mm shell length. Almost all *R. venosa* presented epibionts all over the shell, suggesting an exposed lifestyle. Egg-masses were attached to specimens of *R. venosa*, debris and plastic garbage. The spatial distribution of *R. venosa* within the estuary was coupled with the spatial distribution of *Macra isabelleana*, a typical subtidal bivalve of mixohaline waters. The implications for the food webs of the estuary, including possible predators, are discussed. The presence of *R. venosa* in muddy sediments together with the finding of egg-capsules over the specimens, and the low salinity values at which it is found in the Río de la Plata estuary, confirmed the high plasticity of *R. venosa* and the potential capability of successfully invading novel environments.

KEY WORDS: exotic species, invasion, *Rapana venosa*, Muricidae, Rapa whelk, *Macra isabelleana*, *Ostrea puelchana*, food webs, Río de la Plata, Southwestern Atlantic

INTRODUCTION

The large Asian gastropod *Rapana venosa* Valenciennes 1846 (Neogastropoda, Muricidae) is a predatory mollusc native to the Sea of Japan, Yellow Sea, Bohai Sea and the East China Sea to Taiwan (ICES, 2004). This species was discovered out of its native biogeographic range in the Black Sea, and it has subsequently spread throughout the Sea of Azov, and the Aegean, Adriatic and North Seas (for complete lists of localities see ICES, 2004). The first collection of *R. venosa* in North America was made in the Chesapeake Bay on the East Coast of the United States in 1998 (Harding & Mann 1999). The first report of rapa whelks in South America was made by Scarabino et al. (1999) and Pastorino et al. (2000) from collections in the Río de la Plata estuary, Argentina-Uruguay.

This generalist predator of subtidal mollusks usually feeds on bivalves of economic interest like oysters, mussels and clams (Harding & Mann 1999, Savini et al. 2004), and has been identified as the prime reason for the collapse of several banks of mussels and oysters in the Black Sea (Drapkin 1963, Zolotarev 1996). Adult *Rapana venosa* are found in water temperatures between 4°C and 27°C (Chung et al. 1993) and salinities ranging from 28–33 in Korean waters (Korea Oceanographic Data Center, <http://kode2.nfrdi.re.kr:8001/home/eng/main/index.php>). Furthermore, in nonnative localities *R. venosa* is found in estuarine salinities (Scarabino et al. 1999, Pastorino et al. 2000, Mann & Harding 2000, 2003; ICES 2004). Their high fecundity (Chung et al. 1993), dispersal assisted by a planktonic larvae that is capable of remaining planktonic between 14 and 80 days in estuarine and marine waters (Mann & Harding 2003), and fast growth (Harding & Mann

2005) make *R. venosa* a potentially successful invader worldwide (Savini et al. 2004).

A recent general review of exotic species in the Southwestern Atlantic (34°S to 54°S) revealed that most of the exotic species of the region are concentrated in Buenos Aires Province (northern Argentina), where major commercial harbors are located (Orensanz et al. 2002). At this region, the Río de la Plata (34° to 36°30'S, 55° to 58°30'W) forms one of the largest estuarine systems of South America (ca. 38,000 km² of mixohaline area). This river is one of the large waterways of South America. Two of the major ports in the region, Buenos Aires (Argentina) and Montevideo (Uruguay), lie along its shores generating an intense nautical traffic. The estuary is also the maritime access to the highly complex fluvial system named "Hidrovia," communicating with the Amazon Basin (Bisbal 1995, Mianzan et al. 2001).

Although it is known that ships are one of the main sources of introduction of exotic species via fouling or ballast water, regulations regarding the later in Argentina are not strictly enforced (Orensanz et al. 2002). In agreement, this was the mechanism suggested for the introduction of *Rapana venosa* in the Río de la Plata estuary (Pastorino et al. 2000). Early collections of *Rapana venosa* in the estuary corresponded to adult specimens found in the Rouen and English Banks in May 1998, several egg masses along the Uruguayan coast, between Montevideo and Punta del Este in December 1998 to February 1999 (Scarabino et al. 1999), one specimen (95 mm shell length) in November 1999 off Samborombón Bay (Pastorino et al. 2000), another specimen (89 mm shell length) collected in November 2001 off Montevideo (Rodríguez Capitullo et al. 2002), and recently (spring 2002), several specimens caught in a fisheries research survey along the outer part of the estuary (Carranza et al. in press) (see Fig. 1). However, studies about the potential extent of establishment of this gastropod over time or possible ecological impacts on the food webs of the estuary

are lacking. Therefore, the main goals of this study are to provide data describing the status of *R. venosa* in the Río de la Plata estuary and discuss the potential ecological impact of this species in the region.

MATERIALS AND METHODS

Study Area

The Río de la Plata estuary is an extensive and shallow coastal plain estuary. Its bottom shows a gentle slope with depths lesser than 25 m (10 m mean depth). Fine sediments of fluvial origin occupy most of the estuary, but the outer region is covered by deposits of marine sands (Urien 1972). This estuary is characterized by a quasi-permanent salt wedge regimen. Fresher, and therefore lighter, water flows out of the estuary in the surface layer and a deeper flow brings water from the sea into the estuary. Salinities (hereafter salinity is reported following the Practical Salinity Scale) at the bottom of the estuary range from 0 to >33 (Guerrero et al. 1997). The estuary therefore becomes a typically two-layer system characterized by strong vertical stratification, which gradually weakens seaward. The maximum upriver penetration of the salt wedge is associated to a submersed bar across the river (Barra del Indio shoal). A well-developed turbidity front characterizes the innermost part of the estuary. This turbidity maximum is caused by the flocculation of suspended matter at the tip of the salt wedge, and resuspension of sediment caused by tidal stirring (Franiñan & Brown 1996). A wind driven, two-way discharging pattern has

been described for the estuary (Guerrero et al. 1997). During spring and summer months the river plume moves southward, to the Argentine coast. During fall-winter, the plume manifest mostly towards NNE, along the Uruguayan coast, and can be traced reaching southern Brazil (Piola et al. 2000).

Benthic fauna is characterized by 2 major groups: a low diversity estuarine assemblage (muddy bottoms, salinities between 0.5 and 33), dominated by infaunal bivalves and a marine assemblage (sandy bottoms, salinities >33), with higher values of diversity and the occurrence of oysters and mussels banks (Giberto et al. 2004, Giberto & Bremec In prep.). Bottom type, salinity and the presence of the turbidity front are considered the main physical variables in structuring benthic communities of the Río de la Plata estuary (Giberto et al. 2004).

Sampling and Data Analysis

Rapa whelks and environmental data came from stations sampled during February 2004, December 2005, February and March 2006, in routine fisheries research cruises carried out in the Río de la Plata estuary and adjacent area by the R/V "Capitan Cánepa" (INIDEP) (Table 1). Faunal samples were taken with a bottom trawl designed to capture juvenile fishes (10-mm mesh size). Collected specimens of *Rapana venosa* were frozen on board and examined later at laboratory. For each specimen total weight (shell + body wet weight) (TW), shell length (SL), aperture height (AH), aperture width (AW) and shell thickness (ST) were measured, following Savini et al. (2004). Dimensions were taken using a digital caliper (0.1 mm). The epibiotic invertebrates on the studied material were identified. The number of eggs and capsules of the egg masses were counted and measured under binocular microscope. Fecundity was estimated as total number of eggs in total eggs capsules (see Chung et al. 1993).

The allometric relationship between SL and TW was analyzed with simple linear regression (Sokal & Rohlf 1999).

Oceanographic sampling was performed with a Sea Bird-19 CTD (Conductivity Temperature Depth profiler), at the beginning of each sampling tow. Salinity is reported following the Practical Salinity Scale. Sediment type was characterized using data available from the literature (Urien 1972) and from Giberto & Bremec (In prep.).

To assess potential ecological impacts on the food webs of the area, we analyzed the occurrence of typical subtidal bivalve species, which reach high densities in estuarine and marine adjacent waters (*Macra isabelleana*, *Ostrea puelchana* and *Mytilus edulis platensis*). In doing so, we used macrofauna data (1975–2005) compiled in Giberto & Bremec (2003, In prep.) and Giberto et al. (2004).

RESULTS

A total of 41 rapa whelks and 21 egg masses were collected in summer research cruises between February 2004 and March 2006 (Fig. 2 and Table 2). *Rapana venosa* was found all over the mixo-

TABLE 1.
Summary of sampling data from the Río de la Plata estuary.

Sampling Date	Gear	Depth (m)	Salinity	Temperature (°C)	Sediment
February 2004	Bottom trawl	4–9	13.5–26.7	21.8–23.2	Mud
December 2005	Bottom trawl	8–11	14.8–30.8	17.5–20.4	Mud
Feb–March 2006	Bottom trawl	4–13	12.7–20.3	21.4–22.6	Mud–Sand

haline waters of the estuary, with constant records off Montevideo and in Samborombón Bay. In 2005 and 2006 *R. venosa* was found in southern locations, at higher salinities off Punta Rasa (see Fig. 2 and Table 2). Specimens ranged between 28 and 120 mm SL. SL-frequency and distribution of *Rapana venosa* in the estuary for each cruise is shown in Figure 2. Total weight ranged between 2.8 g and 351.5 g. Figure 3 shows the result of the regression analysis between SL (independent variable) and TW (dependent variable).

Rapa whelks were collected in shallow muddy (36 specimens) and sandy (5 specimens) bottoms. The associated fauna in muddy bottoms were the bivalve *Macra isabellana* (see Fig. 2d), the shrimp *Artemesia longinaris*, the gastropods *Buccinanops* sp. and *Heleobia australis*, the polychaete *Alitta succinea* and the cumacean *Diastylis* sp. In sandy bottoms *R. venosa* was found together with the oyster *O. puelchana* in three sampling stations (see Fig. 2d for the distribution of possible preys).

Undetermined bryozoans (63%) and barnacles (*Balanus* sp., 78%) were the most frequent epibionts colonizing all over the shell of *Rapana venosa* ($n = 36$). Hydrozoan branches (30%) were also

found. Undetermined small sea anemones, undetermined chitons and polychaete tubes (Serpulidae) were found occasionally. Five rapa whelks lack epibionts completely. *Polydora* sp. (Polychaeta) infestations were found in 6 specimens.

A total of 21 egg masses were found. Eight of them were attached to debris and plastic garbage, whereas 13 were found attached to larger whelks. Capsules ($n = 30$) per whole egg mass varied between 108 and 700, and eggs per capsules varied from 434–890. Fecundity estimations were in the range 76,156–85,323 eggs per individual. The egg capsules contained shelled larvae having the operculum and larval shell ($\sim 0.4 \times 0.3$ mm). Larvae with “coned” shells were found with a frequency of $\sim 10\%$ (Fig. 4). Egg capsules from December were pale black color (average of 717 eggs per capsule), whereas several capsules from February were empty with the exit hole bored, or dead with a violet color (average of 568 eggs per capsule), and capsules from March were all empty. Collected capsules, including the curved tip, measured 18.5–29.5 mm in length, and 1.7–2.5 mm in width at the smaller diameter at the base.

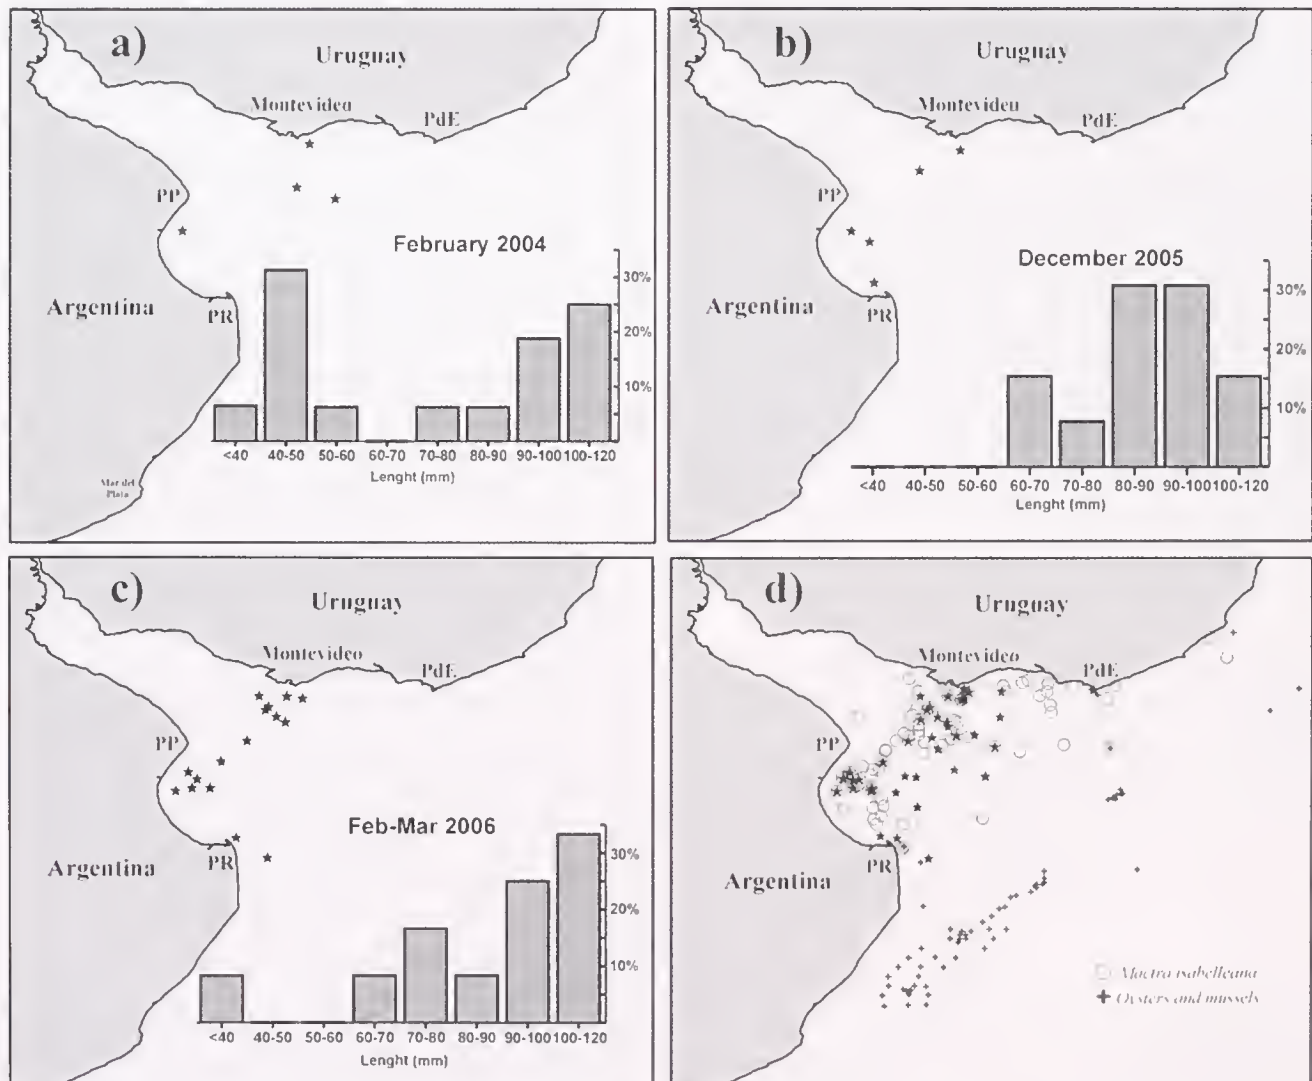

Figure 2. Shell length-frequency and distribution of *Rapana venosa* (★) in the study area during each cruise (a to c). Complete known range distribution of *R. venosa* (★) and potential bivalve preys (banks of *Macra isabellana*, *Ostrea puelchana* and *Mytilus edulis platensis*) (d). PP, Punta Piedras; PR, Punta Rasa; PdE, Punta del Este.

TABLE 2.
Collection of *Rapana venosa* and biometric variables in the Río de la Plata estuary.

Sampling Date	n	Shell Length (mm)	Aperture Height (mm)	Aperture Width (mm)	Thickness (mm)
February 2004	16	36.82–111.92	28.4–94.9	11.3–44.8	0.6–4.9
December 2005	13	68.8–106.8	56–89.2	24.3–41.7	1.6–3.3
Feb–March 2006	12	28.6–119.3	21.5–99.1	9.04–52.5	0.5–3.4

DISCUSSION

The rapa whelk *Rapana venosa* successfully spread over the muddy bottoms of the estuary since their early records off Samborombón Bay and along the Uruguayan coast (Pastorino et al. 2000, Scarabino et al. 1999, Rodríguez Capitulo et al. 2002). Their range extension is now at Argentinean and Uruguayan coastal lines. The finding of invasive marine species in coastal and estuarine waters is an already widespread phenomenon. The impacts of such introductions are unpredictable, and not all of them become a successful resident in the new environments. However, the presence of small specimens of rapa whelk (between 28 and 48 mm SL), and egg capsules with operculated and shelled larvae, confirmed that the population of *R. venosa* is sexually mature and actively breeding in the region, as was suggested in previous works (Scarabino et al. 1999, Pastorino et al. 2000).

Biometric variables measured were in the range reported by Savini et al. (2004) for the Northern Adriatic Sea for similar shell length ranges. Besides their smaller size, the allometric growth of the snails collected in this study presented similar slope values than larger Adriatic species (3.21 and 3.37 for rock and sand samples, Savini et al. 2004). The record of small specimens in other localities where *R. venosa* was introduced is a rare event, because most of the data usually come from commercial fisheries that selectively catch larger snails (Harding & Mann 1999, ICES

2004) or because of possible distinct habitat preferences of juveniles (Savini et al. 2004). However, our data from the Río de la Plata estuary do not show segregation by size classes.

Almost all *Rapana venosa* specimens presented epibionts all over the shell, which suggests an exposed lifestyle. Similar results were found by Savini et al. (2004) for specimens living on hard rock. On the contrary, other studies under field and laboratory conditions found that rapa whelks are nocturnal and remain burrowed most of the day, avoiding settlement by epifaunal biota (Harding & Mann 1999, 2005). Environmental conditions in the Río de la Plata estuary may conduct to a different behavior. The light penetration in mixohaline waters is really poor, with approximately 99% of the incident radiation lost at around 2 m depth (Acha et al. submitted), and the sedimentation rate is high (Urien 1972), which means that adult rapa whelks may be exposed during longer periods of time than in other habitats. It is also remarkable that the organisms that encrust the shells of this gastropod are not usually found in the muddy bottoms of the estuary (Giberto et al. 2004), with the exception of barnacles colonizing small specimens of *Macra isabelleana* (Giberto, pers. obs.). This reflects the lack of hard bottoms in the estuary and the importance of *R. venosa* shells as suitable settlement substrates for epibionts larvae. Moreover, *R. venosa* egg-masses were attached to debris and plastic garbage, which are concentrated over the Barra del Indio shoal by the frontal dynamics (Acha et al. 2003).

Habitat quality is very important for the successful colonization of novel environments. Salinity ranges of the estuary are within the limits at which the species has been found in other locations (ICES 2004), although in this area *Rapana venosa* was always found at low salinity waters (see Table 1 and Carranza et al. in press). Thermal seasonal range of the estuary (10°C to 23°C, Guerrero et al. 1997) is in coincidence with breeding tolerances for *R. venosa* (13°C to 26°C) recorded by Chung et al. (1993). These authors also reported a 17-day incubation period at 18°C to 20°C in laboratory conditions, with females laying egg-masses during all the reproductive period in summer. Specimens of this estuary seem to follow this pattern, because the egg-capsules found in November contained embryos at a morula-gastrula stage (Pastorino et al. 2000), whereas the capsules found in this study (December–February) were with normal and “coned” shelled larvae or empty. “Coned” shells could be malformations leading to nonviable larvae. Egg-masses were attached to specimens of *R. venosa* and debris and plastic garbage, which seems to be an alternative reproductive strategy to deal with the absence of any other primary settlement substrate. These findings are in coincidence with data from the outer estuary by Carranza et al. (in press), which also found egg masses attached to plastic debris and garbage.

The spatial distribution of *Rapana venosa* within the estuary

Figure 3. Linear relationship (data \log_{10} transformed) between shell length (mm) (independent variable) and total weight (g) (dependent variable) for samples of *Rapana venosa* collected in the Río de la Plata estuary between 2004 and 2006. Equation and regression coefficient (R^2) are indicated. SL, shell length; TW, total weight.

Figure 4. Adults of *Rapana venosa* collected in the Río de la Plata estuary over *Mactra isabelleana* banks (a, scale bar: 50 mm). Egg cases were attached to the specimens (b, scale bar: 10 mm) and contained "coned" shells forms and normal shelled larva of 0.4×0.3 mm (c).

was coupled with the spatial distribution of *Mactra isabelleana*. This is in coincidence with the salinity range of 12–30 and the presence of muddy bottoms at which *M. isabelleana* is usually found at high densities (Giberto et al. 2004). It has been proposed that the high abundances of this deposit-feeder bivalve are related to the concentration of organic matter by frontal dynamics, and/or to the retentive properties of the front that could maintain bivalve larvae in this area (Mianzan et al. 2001, Giberto et al. 2004). At the adjacent subtidal marine zones, *R. venosa* was found near oyster (*Ostrea puelchana*) banks. The coexistence of *R. venosa* with these bivalves led to conjecture that it is preying over *M. isabelleana* and *O. puelchana*. Preliminary results on the trophic food webs in the estuary, using stable $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ isotope signatures (Botto et al. In prep.), supported this hypothesis: *R. venosa* ($n = 4$) showed $\delta^{15}\text{N}$ isotopic values in an upper trophic level, over both bivalves signals. Other potential preys could be the bivalves *Erodona macroides*, *Corbula patagonica* and *Nucula puelcha*, which usually inhabit the mixohaline environment (Giberto & Bremec 2003, In prep., Giberto et al. 2004).

Regarding possible predators, it has been suggested that *Callinectes sapidus* could be a control for *R. venosa* in the Chesapeake Bay (Harding 2003), but Cesar et al. (2003) has shown that this crab (which is another exotic species in this estuary) has a diet mainly based on *Limnoperna fortunei*. This is an introduced bivalve typical of low salinity to freshwaters of the Río de la Plata. Other possible natural controls are demersal fishes that prey on the infauna. The whitemouth croaker, *Micropogonias furnieri*, is the dominant species in terms of biomass and sustains the coastal and artisanal fisheries in Argentina and Uruguay (Carozza et al. 2004). *M. furnieri* usually preys on benthic infauna including soft-bodied polychaetes and hard-bodied crustaceans, gastropods and bivalves

like *M. isabelleana* (Puig 1986, Giberto 2001, Giberto unpublished data), using their pharyngeal teeth to crush the hard structures of these invertebrates. Therefore, *M. furnieri* is potentially capable of preying on *R. venosa* juveniles or at least on the egg-masses, the later confirmed recently in diets studies of this croaker (Giberto, unpublished data).

Considering the prolonged larval phase of *R. venosa* (up to 80 days), the lack of potential competitors in the estuary such as stable populations of large gastropods (Giberto et al. 2004, Carranza et al. in press, Giberto & Bremec In prep.), and the impact of the Río de la Plata discharge along the Uruguayan and Argentine coasts, the species is capable of maintaining a source population in the estuary. The vicinity of several other commercial harbors, in combination with favorable oceanographic conditions and food availability leads to the conclusion that viable populations of *R. venosa* are potentially expected in surroundings areas in a short term. The presence of *R. venosa* in muddy sediments together with the finding of egg-capsules over the specimens, and the low salinity values at which it is found in the Río de la Plata estuary, confirmed the high plasticity of *R. venosa* and the potential capability of successfully invading novel environments.

ACKNOWLEDGMENTS

The authors thank Juliana Harding, who provided thoughtful and helpful feedback on early versions of the manuscript, Fabrizio Scarabino for his valuable assistance with the data from Uruguay and Esteban Gaitan for fruitful discussions regarding stable isotopes data. Many colleagues also collaborated in the sampling on board the research cruises. REPRODUCTIVE CYCLE OF THE PURPLE SNAIL *PLICOPURPURA PANSA* (GOULD 1853) FROM TWO LOCATIONS AT BAJA CALIFORNIA SUR, MEXICO

LUDWIG C. A. NAEGEL* AND FEDERICO A. GARCÍA-DOMÍNGUEZ

Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional Apdo. Postal 592,
La Paz, B.C.S. 23000 Mexico

ABSTRACT The reproductive cycle of purple snail, *Plicopurpura pansa* (Gould 1853), sampled randomly monthly over a period of 20 mo at Playa Cerritos at the Pacific, and Punta Perico at the Gulf of California, Baja California Sur, Mexico, was examined by histological observations of the gonadal development. At both sites year-round copulations were observed, whereas egg capsules could be found only during February to May. During nearly the whole period, male and female gonads were found in the developing stage. From January to July and August most female gonads were found in the ripe, and from January to June and August in the spawning stage. Male gonads in the spawning stage were observed from December to September. The recovering stage was found in male and female gonads between September and October. Synchronism of gonadal development between both sexes was evident. Spawning could be observed in females with a total shell length of more than 18 mm, whereas smaller animals had gonads in the developing stage. In gonads of males signs of spawning could be observed in animals larger than 18 mm. No relationship was found between the water temperature and the spawning period. The sex ratio was 1:1 at Playa Cerritos, whereas at Punta Perico more males than females were counted.

KEY WORDS: reproductive cycle, purple snail, *Plicopurpura pansa*, Muricidae

INTRODUCTION

Most marine snails of the family Muricidae, if not all, produce in the hypobranchial gland a colorless secretion that turns on exposure to air and light to “Tyrian Purple” (Fretter & Graham 1994). For its dye the carnivorous, gonochoristic muricid *Plicopurpura pansa* (Gould 1853), which inhabits intertidal rocky shores exposed to high impact waves of the open sea, has been exploited on the Pacific coast from Central America to Mexico for hundreds of years by indigenous communities for dyeing threads of cotton to be woven afterwards into traditional dresses. However, in recent years in Mexico the commercial exploitation of the purple snail for dyeing kimonos with “Tyrian Purple” had reached such levels as to threaten the survival of the species, and in 1988 the Mexican government declared *P. pansa* a protected species (Anonymous 1988, 1994).

Despite the recent concerns about the state and recovery of *P. pansa*, little is known about the principal life-history features. The impeded accessibility, only during extreme low tides, is the main reason for the difficulties of *P. pansa* field research. Detailed information on the reproductive strategy however, is a prerequisite for the development of techniques for restocking natural populations and to facilitate effective management.

In Mexico, some information about the gonad reproductive cycle of the purple snail *P. pansa* is available from Oaxaca (Hernández-Cortés & Acevedo-García 1987, Acevedo-García et al. 1993), a histological study from Nayarit (Quiroz-Rocha 1992), and a detailed study about the reproductive cycle from Sinaloa (González-Flores 1997). Especially, the understanding of the reproductive cycle and the spawning period of *P. pansa* will provide the necessary information needed for the determination of the recruitment period of natural populations. Up until now data are missing about the reproductive cycle of *P. pansa* from Baja California Sur, the most northern area of its distribution. The objectives of this study were to determine over a period of 20 mo the reproductive cycle of *P. pansa* at two locations in Baja California

Sur. Additional information on minimum size at sexual maturity and sex ratio is needed to facilitate efficient management of this natural resource.

MATERIALS AND METHODS

Sampling

Preliminary trials were started from January to May 2000 to determine the best location and period for the collection of *P. pansa*, whether egg capsules can be found, and to assess the method of sampling to obtain statistically valid data. From intertidal rocks at days during extreme low-water spring tides at Playa Cerritos at the Pacific coast (23°19'54"N and 110°10'38"W) and at Punta Perico at the Gulf of California (24°01'54"N and 109°48'21"W; Fig. 1), 20–30 specimens from 100–300 animals of unexploited populations of *P. pansa* were randomly selected from June 2000 to January 2002, monthly, with the help of a table of random numbers. At Playa Cerritos a total of 592 were randomly selected during 20 mo and at Punta Perico a total of 596 specimens.

During sampling the water temperature was recorded, whether egg-capsules could be found and whether copulas were observed. Injecting a 10% neutral buffered formalin solution into the snails preserved the tissue of the animals. Subsequently about 24 h later in the laboratory the total SL of the animals was determined from the apex to the end of the siphon channel with the help of a digital caliper with a precision of 0.01 mm, the shell was broken and the gonads and the digestive gland were removed. Table 1 shows the number of gonads examined, the average total SL with standard deviation, and the size range. Sex determination was accomplished by visual inspection for a penis, and verified by histological examinations of the gonads.

Observations by Light Microscopy

The gonads were dehydrated in the alcohol series, cleared with butylated hydroxyanisole, and embedded in paraffin. The sections (7–9-µm thick) were prepared from the thickest part of the gonads, and subsequently, according to the methodology described by

*Corresponding author. E-mail: lnaegel@ipn.mx

Figure 1. Map showing the study sites.

Luna (1968), stained with Harris hematoxylin and contrasted with eosin. This method was adopted after verifying in four specimens, that gonadal maturity was uniform in different parts of the gonad. Both sexes were confirmed by light microscopic examination of histological preparations of the gonads. Light micrographs were taken with a digital camera (Olympus Camedia C-5060) mounted on a light microscope (Olympus BX 41).

Reproductive Cycle With Gonad Developmental Phases

To determine the seasonality and duration of the reproductive cycle from the histological preparations the development of the gonads is classified arbitrarily: in females it is divided into four successive stages (developing, ripe, spawning, recovering), in males only into 3 (developing, spawning, and recovering) stages.

Developing Stage

In female gonads in the developing stage can be found oögonia and developing oocytes (Photo 1a). The size of the gonads is increasing through the accumulation of growing oocytes accumulating yolk. The oocytes are predominantly previtellogenic. In male gonads can be observed the spermatogenic follicles, spermatogonia, spermatocytes, and spermatozoa arranged in characteristic bands (Photo 2a).

Ripe Stage

In females, all follicles are filled with ripe vitellogenic oocytes of polygonal shape containing mature yolk granules (Photo 1b). No empty space was observed between the follicles. In males, the ripe stage cannot be distinguished from the developing stage, and is therefore omitted.

Spawning Stage

In females, because most oocytes in the follicles are discharged into the environment, the lumen of the follicles becomes essentially empty. Spawning ovaries are characterized by the presence of spaces between the free oocytes in the lumen (Photo 1c). In males, the lumen of the follicles is partially empty with spaces inside, and a decrease in the quantity of spermatozoa can be noticed. The spermatocytes remain at the follicular walls (Photo 2b). In this stage the spermatic ducts are filled with spermatozoa (Photo 2b and 2c).

Recovery Stage

In males and females, after spawning the gonads are collapsed, and each follicle is empty. In females few residual oocytes are present, being phagocytized by amoebocytes. The gonads are reduced to a thin layer of tissue adjoining the hepatopancreas (Photo 1d). No active oögenesis is evident. In males phagocytosis occurs of the residual spermatozoa by amoebocytes, and no active spermatogenesis are evident. However, not in all samples in the recovery stage are the gonads visible because they have been completely absorbed and therefore it is only possible to determine anatomically the sex of the animals by the presence or absence of a penis.

Mean Maturity Index

Grant and Tyler (1983) proposed using the term "maturity index" for examinations of gonad histological sections and restricting the use of "gonad index" to the quantitative analysis of relative gonad weight or size. We obtained the mean maturity index for each monthly sample, according to the method described by Seed (1976) and Kautsky (1982) for the bivalve *Mytilus edulis* (Linné 1758). The number of animals in each stages of maturity was multiplied by the numerical ranking of the stage (recovering = 1; developing = 2; ripe = 3; spawning = 4) and by dividing the sum of these products by the number of individuals in the sample. The index varies from one, if the female gonads of the entire population are recovering and 4 if the whole female population is spawning. In the male population, because the ripe stage is missing, the index will be 3 if all animals are in the spawning stage, and 1 if all animals are recovering.

Biological Minimum Size at Sexual Maturity

To determine the minimum size at sexual maturity we selected from all collected animals the 10 smallest females and males from each location and determined their stage of gonadal maturity.

Sex Ratio of the Histologically Examined Specimens

The total number of males and females collected at Punta Perico and Playa Cerritos was subjected to the χ^2 test to examine whether statistically significant differences exist between the numbers of the different sexes examined histologically.

RESULTS

Copulation, Egg Capsule Deposition, and Water Temperature

During the collection of the snails we observed at Playa Cerritos and at Punta Perico year-round copulations, whereas egg capsules could be found on both sites only during February to May. During this period at Punta Perico water temperatures of

24°C to 26°C were measured. The water temperature in summer reached up to 32°C. At Playa Cerritos slightly lower water temperatures were measured: January up to May of 19°C to 20°C, and during summer up to 28°C (Fig. 2). No relation could be determined between the water temperature and the copulation and capsule deposition.

Color of the Gonads

Marked variations in the color of the gonads could be observed during different sampling dates. During September to October the

gonads were dark brown, and no sexual differences could be observed. In contrast from November until April the female gonads were yellow, whereas the male gonads were brown. The histological observation that the gonadal maturity is uniform in different parts of the gonad confirmed the uniform coloration of the formal-fixed gonads.

Sex Ratio

In this 20-mo study we examined histologically 544 gonads from snails collected at Playa Cerritos (260 females, 284 males)

Females

Photo 1. Light micrographs from histological sections of gonads from female *Plicopurpura pansa* snails. Scale bars = 100 μ m. (a) Developing stage: Yolk (Y), Previtellogenic oocytes (Po), Growing oocytes (Go). (b) Ripe stage: Vitellogenic oocytes ready to be released (Vo). (c) Spawning stage: Empty spaces and remains from broken can be observed. (d) Recovering stage: Residual oocytes (Ro), Hepatopancreas (Hp).

and at Punta Perico 543 specimens (221 females, 322 males). Applying the χ^2 test we examined the hypothesis that the sex ratio is 1:1. For the animals from Playa Cerritos the calculated P value was 0.3 showing that no statistically significant differences existed between the number of males and females. In contrast at Punta Perico were found statistically significant differences in the sex ratio ($P < 0.001$). More males than females were found.

Males

Photo 2. Light micrographs from histological sections of testis from male *Plicopurpura pansa* snails. Scale bars = 100 μ m. (a) Developing stage: Testis with different stages of spermatogenesis within the spermatid tubule. In the lumen of the spermatid tubule (Lst) can be observed spermatozoa (Sp) arranged in bands. (b) Spawning stage: In the lumen of the spermatid tubule (Lst) are few spermatozoa (Sp) visible. (c) Spawning stage: The lumen of the spermatid duct (Lsd) is filled with spermatozoa (Sp). (d) Recovering stage: Residual gonad tissue (Rgt), Hepatopancreas (Hp).

Gonad Reproductive Cycle

Punta Perico

In gonads from female snails collected at Punta Perico the developing stage was found nearly during the whole sampling period, with the exception of September to October 2000, and October 2001. In December 2001, 90% of the nine examined female gonads were in the developing stage. Female gonads were found in the ripe stage from June to August and November 2000, and from February to June 2001 and in January 2002, with the highest percentage in June 2000 (40% from 7 animals) and in February 2001 (36% from 11 animals).

Female gonads in the spawning stage were observed from June to August 2000, January to September 2001 and in January 2002. The highest frequency of spawning occurred in August 2000 and March 2001 (41% from 12, and 60% from 10 animals, respectively). Female gonads in the recovery stage were observed during nearly the whole sampling period, with the exception of June 2000 when no gonad was found in the recovery stage. In September to October 2000 and in October 2001, 100% of the 32 samples studied were in the recovery stage (Fig. 3a).

Male gonads from snails collected at Punta Perico were in the developing stage during the whole observation period, with two

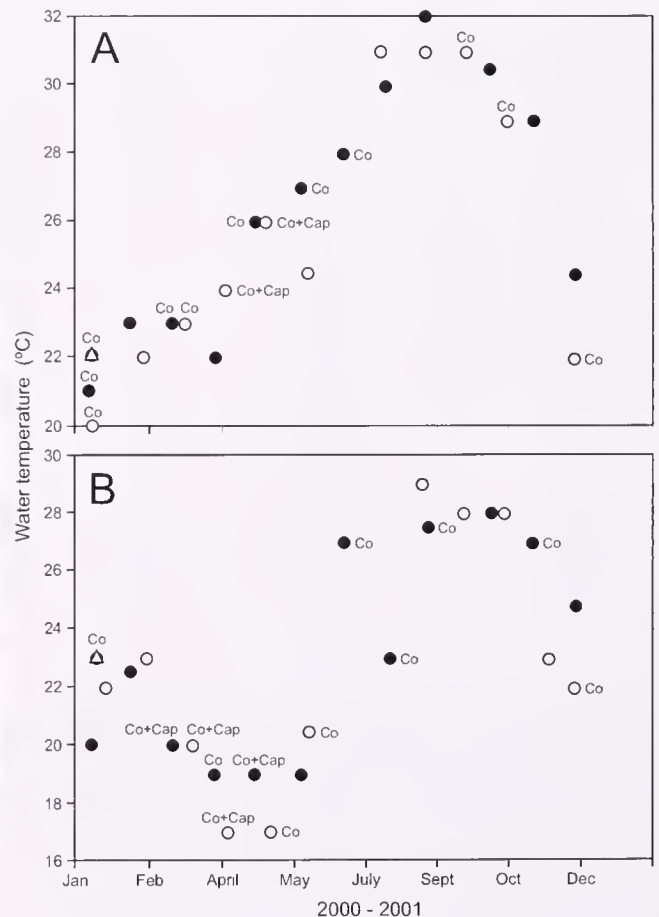

Figure 2. Copulation, egg capsule deposition of *Plicopurpura pansa*, and water temperatures at Punta Perico (A) and Playa Cerritos (B). Water temperature: \circ , 2000; \bullet , 2001; \triangle , 2002; Co = Copula; Cap = Capsules.

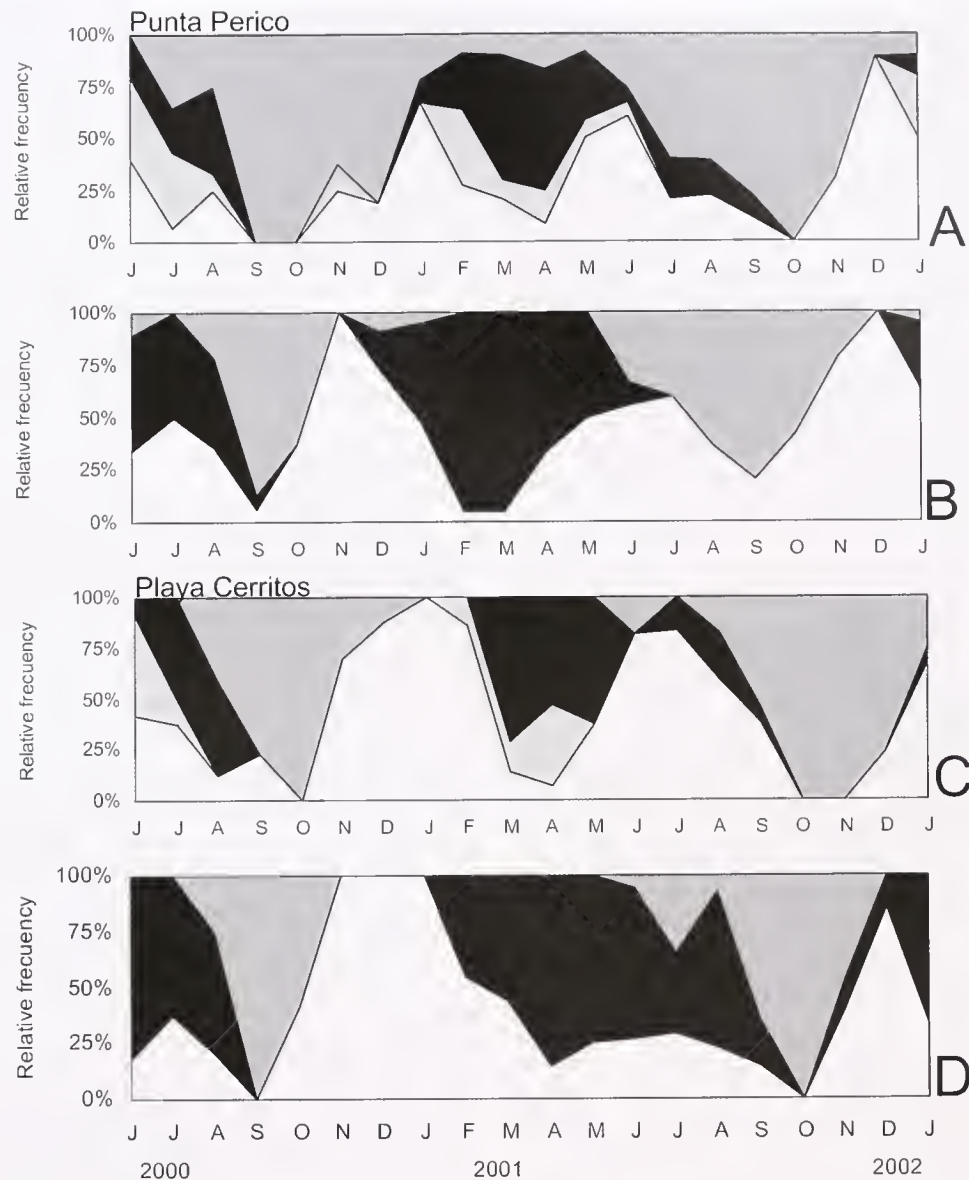

Figure 3. Male and female reproductive cycle from *Plicopurpura pansa* collected during the period from June 2000 to January 2002 at Punta Perico (A = females, B = males) and Playa Cerritos (C = females, D = males). □, Developing; ■, Spawning; ◻, Ripe; ▒, Recovering.

peaks of 100%: one in November 2000 (12 gonads studied) and another in December 2001 (19 gonads examined).

Individuals in the spawning stage were found during two clearly defined periods, one from June to September 2000, and another one from December 2000 until June 2001. Also in January 2002 the beginning of another spawning stage was seen. One spawning peak was found in February to March 2001 with 95% from a total of 39 male gonads studied. In September 2000, 87% of the 16 male gonads were examined in the recovery stage, and in September 2001 80% from a total of 15 gonads (Fig. 3b).

Playa Cerritos

Female gonads in the developing stage could be observed during the whole sampling period, with the exception of October 2000 and October to November 2001. Two peaks occurred, one in Janu-

ary and another in June to July 2001. In January 2001 all 15, and in June to July 82% from the 23 examined female gonads were in the developing stage.

The ripe stage of the female gonads showed two peaks of activity: one in June 2000 with 50% (12 gonads examined) and another in April 2001 with 40% from 12 examined gonads.

The spawning stage was observed between June up until August 2000 and March up until September 2001. In August 2000 from 17 examined gonads, 47% were in the spawning stage; in March 2001 from 14 examined gonads, 71% were in the spawning stage, and in August 2001 from 17 observed gonads, 24% were in the developing stage.

The recovery stage was observed during the periods; from August to December 2000 with a peak in October (100% from 12 examined gonads), and June 2001 to January 2002 with a peak in

October to November 2001 (100% from 26 examined gonads) (Fig. 3c).

The male gonads in the developing stage were observed for the whole sampling period, with the exception of September 2000 and during October 2001. Two peaks of activity were observed: in November, December 2000, and January from 38 examined male gonads were all 100%, and in December 2001 from 14 gonads 86%, in the developing stage.

Spawning took place from June to August 2000, with a peak in February 2001 (100% from 15 examined gonads), and from February to September 2001, with a peak in April 2001 (85% from 14 examined gonads).

The recovering stage was mainly observed from August to October 2000, with a peak in September 2000 when all (100%) of the 10 examined gonads was in the recovering stage. In 2001 the recovering stage was observed from July to November with peaks in September (64% from 14 examined gonads) and October (100% from 19 examined gonads; Fig. 3d).

Mean Maturity Index

Insight into the reproductive cycle of *P. pansa* was obtained from the combination of the monthly assessments of the gonad reproductive cycle and the monthly mean maturity index.

The mean maturity index for female gonads collected at Playa Cerritos had values above 2 during January to August, with peaks in February and March, demonstrating that the majority of the snail population was in the ripe and spawning stage. In September to October the majority of the gonads are found in the recovering

stage (Fig. 4b). The situation of the mean maturity index of the male gonads is very similar. From December to August the majority of the population is in the spawning stage, and from September to October the gonads are recovering.

The majority of the female gonads from snails collected at Punta Perico had during January to August a mean maturity index >2.0, demonstrating that they were, like at Playa Cerritos, in the ripe and spawning stage. An index value below 2.0, as observed from September to December, showed that they were in the recuperating stage (Fig. 4a). The same situation can be found in male gonads: the majority of the population was in the spawning stage during November to July, and only during August to October in the recovering stage. The data on the mean maturation index agreed well with the histological results described previously.

Size at Sexual Maturity

The 10 smallest female snails from the 260 females collected at Playa Cerritos had a total SL between 13.0–19.08 mm, and the size of the 10 smallest males from 284 animals SL ranged from 14.86–18.56 mm. In the females the gonad development stage was up to 18.77 mm SL, either recovering or developing. Spawning could be observed in females larger than 18.84 mm. In males, spawning could only be observed in animals larger than 18.00 mm. A similar situation could be observed from the snails collected at Punta Perico. The size of the 10 smallest females from 221 animals collected ranged from 16.37–21.00 mm and the size of the 10 smallest males from 322 animals ranged from 14.8–19.6 mm. Only one female of a size of 17.3 mm showed gonad development, larger animals were in the developing, ripe, spawning, or recovering stage. The gonads of the males were either in the developing (7) or in the recovering (2) stage. One male snail with a size of 18.94 mm had a gonad with signs of having spawned.

DISCUSSION

Reproductive Cycle of *P. pansa*

The timing and duration of the reproductive cycle of *P. pansa* from gonad development through developing, ripe, spawning, and recovering is controlled by an interaction of environmental and endogenous factors. Activation of the gonads is probably controlled by endocrine hormonal factors being initiated in connection with lowered water temperature. With increasing air and water temperatures gonad development is starting and rapidly leading to maturation. Such effects were noticed by Chung et al. (2002) during studies of the reproductive cycle of the Korean muricid *Rapana venosa* (Valenciennes 1846). Kautsky (1982) made similar observations with the bivalve *Mytilus edulis*. Detailed information about the reproductive cycle of *P. pansa* is only sparingly available, mainly as thesis work, and it is difficult to compare one study with the other. Hernández-Cortés and Acevedo-García (1987) mention that copulation of *P. pansa* occurs at the Pacific coast of Oaxaca during the hot season from March until July, with the peak of occurrence in May, and from June to July the females are laying their egg capsules. Similar observations from Oaxaca are reported by Turok et al. (1988), who additionally mention that the peak of capsule deposition is in June, and that this continuous activity leads to a constant production of young animals during July, up until September.

In a histological study about the gonad development of *P. pansa* collected in Nayarit, Quiroz-Rocha (1992) reported

Figure 4. The mean maturity index for male and female gonads from *Plicopurpura pansa* collected at Punta Perico (A) and Playa Cerritos (B).

that during December to January the gonads are in the resting (immature) stage and that spermatozooids can be scarcely found in male gonads. During May to July the gonads are in the developing stage, and reaching the ripe stage during August to September. In a more detailed histological study about the gonad development cycle of *P. pansa* further north from Sinaloa, González-Flores (1997) reported that the recovering period occurs from September to October, but can be extended up until November to December. The developing stage can be observed in January to February but possibly can be extended during the whole year.

Copulation and the ripe stage of the gonads can be observed from March until July. Spawning starts in May and lasts until July. Acevedo-García et al. (1993) report, that females larger than 2 cm lay egg capsules during December up until September. In our study however, we could show that *P. pansa* can reproduce during the whole year with the highest frequency of spawning occurring in March and August. For adequate natural resources management of *P. pansa* in Baja California Sur, strict prohibitory measures should be enforced for exploiting animals during the developing, ripe, and spawning stages of the gonads, and only after special considerations should collections be permitted from September to October, when the animals are in the recovering stage.

Influence of the Water Temperature on the Reproductive Cycle

In most prosobranchs the reproductive cycle is in synchrony throughout a population, controlled by some kind of exogenous and/or endogenous controlling mechanisms (Webber 1977). Important exogenous factors for the gonad development of marine gastropods are considered to be temperature, nutrition, and photoperiod (Webber 1977, Martel et al. 1986). In temperate climates the seasonal changes of the temperature together with changes in the photoperiod are considered important factors controlling the gonad development, however in tropical zones where seasonal temperature fluctuations are less pronounced, temperature does not have such a marked impact. Many species have a seasonal spawning cycle spawn during springtime, and some even in winter (Webber 1977). In Argentina, in the southwestern Atlantic Ocean (Mar del Plata), *Zidonia difresnei* (Donovan 1823) spawns during spring and summer (Giménez & Penchaszadeh 2002). In Coquimbo, North Chile, the subtidal gastropods *Priene scabrum* (King 1832) spawn in winter, and *Siman cymba* (Menke 1828) during almost the whole year (Romero et al. 2003). At the Pacific coast of Bahía Tortugas, Baja California Sur, Mexico, the wavy turban snail *Astrea undosa* (Wood 1828) spawns during the whole year, with spring and autumn as the major intensive spawning seasons (Belmar-Pérez et al. 1991). In Oaxaca Hernández-Cortés and Acevedo-García (1987), as well as González-Flores (1997) observed in Sinaloa the main spawning season of *P. pansa* is during the summer months of May to July. In Baja California Sur *P. pansa* has a spawning season from January to July until August, however, mainly in February to April during relative cold, and July to August during warm water and air temperatures. The gonad reproductive cycle of *P. pansa* seems therefore to be correlated with the temperature. The time of spawning of *P. pansa* might also be correlated with periods of decreasing differences between low and high tides. A decrease in the tidal range is observed in January to March and June to July up until September. During these periods the laid egg capsules are located either a short distance under the water surface or in water-splashed areas.

Sex Ratio

Differences in the sex ratio of a mature population of gonochoristic species can be used to check whether there is differential growth or mortality rate between the two sexes (Gimin & Lee 1997). In this study we examined the gonads from 284 males and 260 females collected at Playa Cerritos and no statistically significant difference was detected in the ratio between males and females. Also in Jalisco no difference in the male to female ratio could be found (León-Alvarez 1989). However, at Punta Perico a significant statistical difference in the male/female ratio (1:0.74) was observed. At this location we examined the gonads from 322 males and 221 females. The difference in the male/female ratio could be explained by the different conditions of the rocky shore at Playa Cerritos and Punta Perico. At Playa Cerritos, even at high tides, all the rocks are never completely submerged the water. In contrast, at Punta Perico, during high tides a great part of the shore is totally submerged and offering only limited hiding places to the snails, which need protection against displacement by the strong impact of the waves. To avoid the displacement by strong wave actions the snails prefer protective areas where they can hold fast onto the substrate (Hernández-Cortés & Acevedo-García 1987). Because females reach larger sizes, they are more endangered to be displaced by wave actions and currents than males (Denny et al. 1985). Although the reason is not mentioned, both Hernández-Cortés & Acevedo-García (1987) and Alvarez-Díaz (1989) reported that on the Pacific coast of Michoacan, males can be found in greater numbers than females (1: 0.83) and (1:0.75), respectively. Similar results were obtained by Turok et al. (1988) (1:0.78). Hernández-Cortés, and Acevedo-García (1987) in Oaxaca; and in Jalisco by Reyes-Aguilera (1993) (1:0.84), Fonseca-Madriz (1998) (1:0.72), and by Michel-Morfin et al. (2000) (1: 0.75). Another explanation for the occurrence of more anatomical males than females in a sample could be imposex, caused by the organic metal compound, tributyltin, which is used as a antifouling paint in shipyards, and which is leading to erroneous classification of males and females, resulting in a higher number of males (Gooding et al. 1999, Penchaszadeh et al. 2001). The comparison of our visual anatomical inspection of the animals with the histological examinations of the gonads show that the differences in the dominance of males at Punta Perico cannot be explained by imposex. The collection of the purple snail by fishermen as a bait and even as a specialty food could also be a reason for an unequal sex ratio. Fishermen prefer larger animals, and for this reason female snails are more sought after. In Punta Perico the population of *P. pansa* is not exploited by fishermen, and only environmental conditions could explain the unequal sex ratio observed there.

Minimum Size at Sexual Maturity

The determination of the minimum size at sexual maturity of any species of commercial interest is an important parameter for considerations of management and exploitation. Only fragmented results are available about the life history of *P. pansa*. After spawning, intracapsular development until hatching takes six to eight weeks at 22 °C (Naegel et al. 2003, Naegel 2004, Naegel & Gomez del Prado-Rosas 2004). The duration for settling and metamorphosis of the veliger larvae after spawning takes at least the same length of time (Naegel et al. 2003). The growth, environmental optimal range, and food requirements of the settled juvenile

niles smaller than 6 mm are as yet unknown. Certainly, for a snail to reach this size after spawning more than one year is needed. In this study we show that juveniles of *P. pansa* do not reach sexual maturity until they reached a size of more than 18 mm. It can be concluded that the purple snails begin to spawn when they reach a size of at least 18 mm. At this size they are at least two or three years old (Ramírez-Rodríguez & Naegel 2003). This extremely slow growth and long period before reaching sexual maturity could be caused by the harsh intertidal environmental conditions, such as the risk of desiccation and overheating through several hours of daily exposure to air, sun, and current reversal during the tidal cycle. Similar observations were made with the mangrove snail *Thais kioskiformis* (Duclos 1832), which showed a growth of only ~1 mm/year, and reaches the onset of sexual maturity at a SL of ~24 mm (Koch & Wolff 1996).

In view that *P. pansa* is in Mexico, because of over-exploitation in the past, today a species under special protection, and in view of the extremely slow growth rate, collecting snails <18 mm can potentially cause a drastic reduction in recruitment, and for this reason should not be permitted.

ACKNOWLEDGMENTS

The authors thank Jorge López- Rocha for his valuable help during the snail collections and for his excellent histological work. The authors also thank Oscar Armendariz for drawing the figures and Chris Cooksey (London) for proof reading of the manuscript. The study was financially supported by a grant from the Conchologists of America, Inc., US-MEXUS, and by CONACYT (Project 31566 N). Both authors received grants from the Instituto Politécnico Nacional (COFAA, EDI).

ABSTRACT Neutral red retention (NRR) assay was used to evaluate the effect of changes in water temperature on lysosomal membrane integrity in the hemolymph of blacklip abalone, *Haliotis rubra*. Results from gradual temperature changes between 7 °C and 16 °C and between 16 °C and 25 °C showed that water temperatures within the range of 15 °C to 17 °C were optimal for maintaining lysosomal membrane integrity in this species. The rapid temperature changes between the ranges used in the gradual temperature change experiments indicated that when abalone were transferred directly between these temperatures their NRR time gradually increased or decreased to the level corresponding with the new temperature. However, when abalone were transferred directly between 7 °C and 25 °C or between 11.5 °C and 20.5 °C their NRR times initially decreased significantly, and then gradually increased to the levels corresponding with the new temperatures, indicating that different ranges of water temperature change can affect the lysosomal membrane integrity differently. The NRR times of blacklip abalone at 7 °C, 16 °C and 25 °C were 40.0 ± 2.89 min, 113.33 ± 3.85 min and 35.0 ± 2.89 min, respectively.

KEY WORDS: neutral red retention assay, lysosomal membrane stability, temperature, blacklip abalone, *Haliotis rubra*

INTRODUCTION

The blacklip abalone, *Haliotis rubra*, is a marine mollusc found in the southern waters of Australia (Shepherd 1975). This temperate species predominantly inhabits rocky inshore waters between 5 and 30 m in depth (Shepherd 1975), where the water temperatures range from 8 °C to 22 °C (Gilroy & Edwards 1998, Shepherd & Hearn 1983). This species is also economically important, worth millions of export dollars a year to Australia (Drew et al. 2001). During the last decade blacklip abalone aquaculture has developed substantially and has become one of the main abalone species farmed in Tasmania and Victoria. Most commercial operations in Australia use land-based raceway systems in the grow-out phase, where the water temperatures can drop to 7 °C in winter and increase to as high as 25 °C in summer (A. Butterworth pers. comm.).

The published data showed that some abalone species had little tendency to adapt to chronically altered thermal environments and little ability to withstand acute thermal shock (Gilchrist 1995). For example, Prince et al. (1987) found that the presence of warmer water in the north and northeast of Tasmania was the main reason for the stunted growth of the wild blacklip abalone in the region. Unusual high water temperatures in summer were suggested by Winstanley (1972) as one of the major factors causing high abalone mortality in some regions of Australia. Correlations between high seawater temperature and increased mortality were also established in the experiments with the Californian black abalone *H. cracherodii* (Steinbeck et al. 1992). Cheng et al. (2004) noted that when the Taiwanese abalone (*H. diversicolor supertexta*) was subjected to elevated water temperatures they were more susceptible to *Vibrio parahaemolyticus*.

Lysosomes are polymorphic, hydrolytic enzyme-containing organelles with many intracellular and extracellular roles (De Duve & Wattiaux 1966). In molluscs, one of the main functions of lysosomes is to digest macromolecules and break down damaged or old cell parts as well as destroy foreign invaders such as bacteria and viruses (Hauton et al. 2001). Neutral red retention (NRR)

assay measures the retention time of the neutral red dye in the lysosomes. In unstressed cells lysosomes will accumulate and retain the neutral red dye for an extended period of time. Once destabilized by a stress response the neutral red dye will leak into the cytosol of the cell through the damaged lysosomal membrane (Moore 1980, Pipe 1987, Lowe et al. 1995a, 1995b). As stressed cells lose their dye at a faster rate than nonstressed cells the rate of NRR in the lysosome can therefore be correlated to the overall stress of the animal (Harding et al. 2004a). Compared with other methods of measuring stress in molluscs NRR assay is convenient and inexpensive, thus this methodology is increasingly being applied as an index to evaluate environmental, physiological and mechanical stresses (Hauton et al. 1998, 2001). NRR assay has been used in assessing responses to various contaminants in mussels and freshwater snails (Lowe & Pipe 1994, Lowe et al. 1995a, b, Mamaca et al. 2005, Svendsen & Weeks 1994), to seasonal and environmental changes associated with the reproductive cycle, temperature, air exposure and food availability in mussels and oysters (Harding et al. 2004b, Zhang et al. 2006) and to mechanical disturbances related to grading, postharvest processing activities and storage conditions in mussels and oysters (Harding et al. 2004a, Zhang & Li 2006).

The main objective of this study is to investigate if NRR assay could be used to evaluate the effects of water temperature change on blacklip abalone *H. rubra* and their responding patterns in controlled experiments.

MATERIALS AND METHODS

Experimental Animals

The abalone used in this study were obtained from a commercial farm located in Victoria and were approximately four years of age. Their height, length and width (mean \pm SE, $n = 100$) were 29.15 ± 0.60 mm, 93.71 ± 1.16 mm and 71.94 ± 0.89 mm, respectively. During the experimental period the abalone were held in 500 L tanks and fed on a standard artificial abalone diet provided by Adam & Amos Abalone Diets (Mt Barker, Adelaide, South Australia).

Neutral Red Retention Assay

The Neutral red retention (NRR) assay used in this study was modified from the methods used by Lowe et al. (1995a, 1995b), Hauton et al. (1998, 2001) and Zhang et al. (2006). The neutral red stock solution was made by dissolving 2.28 mg of neutral red powder in 1 mL of dimethyl sulphoxide (DMSO). The working solution (0.01 mg mL^{-1}) was prepared by diluting 17 μL of the stock solution with 4 mL of artificial saline solution consisting of $0.48 \text{ g L}^{-1} \text{ CaCl}_2$, $1.45 \text{ g L}^{-1} \text{ MgSO}_4$, $2.18 \text{ g L}^{-1} \text{ MgCl}_2 \times 6\text{H}_2\text{O}$, $0.31 \text{ g L}^{-1} \text{ KCl}$, $11.61 \text{ g L}^{-1} \text{ NaCl}$, and $0.35 \text{ g L}^{-1} \text{ NaHCO}_3$ (Buchanan et al. 2001).

Abalone hemolymph (0.2 mL) was drawn from the cephalic arterial sinus at the anterior end of the foot using a 29 G \times 1-mL syringe. The hemolymph was then placed into a 2 mL siliconized Eppendorf tube containing 0.2 mL of artificial saline solution and gently mixed. Each abalone hemolymph sample was collected within 1 min to minimize the potential effects from handling. A 40- μL mixture of the hemolymph sample and artificial saline solution was then placed onto a microscope slide treated with a poly-L-lysine solution (20 μL poly-L-lysine in 100 μL distilled water). The slide was then placed into a 10°C lightproof humidity chamber for 15 min to allow the cells to adhere to the slide. After 15 min the slide was removed from the chamber and the excess hemolymph was removed, 20 μL of neutral red working solution (10°C) was then added to the cell layer and incubated in the chamber for another 15 min. A cover slide ($22 \times 22 \text{ mm}$) was then placed onto the slide and the hemocytes were examined using a compound microscope ($\times 400$ magnification). The slide was examined at 15 min intervals for the first 60 min and then every 20 min. A total of 50 granulocytes per individual were examined at each time interval. Once 50% of the hemocytes had started to lose dye from their lysosomes the assay was stopped and the time for the previous examination was recorded as the NRR time. The observer was not informed of the origin of the sample under examination to minimize the possibility of biased assessment.

The Effect of Water Temperature Change on Lysosomal Membrane Stability

In this study each temperature treatment group was replicated three times by using three 500-L flow through tanks. Prior to each treatment 60 tagged abalone per replicate were acclimated at the required starting temperatures for seven days. At each sampling time hemolymph was taken from three randomly selected abalone in each replicate, with each of these abalone sampled once only.

Gradual Water Temperature Change

The gradual water temperature change experiment consisted of two treatments. In the first treatment, abalone acclimated at 16°C were split into three groups. The first two groups were respectively subjected to a gradual increase or decrease in water temperatures, whereas the third group was maintained at 16°C as a control. A temperature change rate of 1°C every two days was applied in the first two days and was changed to 2°C every two days thereafter until the final temperature of 7°C or 25°C was reached. In the second treatment abalone were also separated into three groups. In the first group abalone acclimated at 7°C were subjected to a gradual increase, whereas in the second group abalone acclimated at 25°C were subjected to a gradual decrease in water temperature until the final temperature of 16°C was reached in both groups. A temperature change rate of 2°C every two days was used until

15°C or 17°C was reached and then changed to 1°C every two days to the final temperature of 16°C . The third group was maintained at 16°C as a control. Hemolymph was sampled 48 h after the required temperature change. Once the final temperatures were reached the abalone were maintained for a further 6 days with hemolymph samples taken every 48 h during this period. The control samples were collected at each sampling time from the 16°C tanks.

Rapid Water Temperature Change

The rapid temperature change experiment consisted of four treatments. In the first treatment, abalone acclimated in 16°C water were split into two groups and transferred into 7°C and 25°C water respectively. In the second treatment two groups of abalone were acclimated at 7°C and 25°C respectively and then transferred directly into 16°C water. In the third treatment the first group was acclimated at 7°C and placed directly into 25°C water, whereas the second was acclimated at 25°C and placed into 7°C water. In the fourth treatment the abalone acclimated at 11.5°C were placed directly into 20.5°C water, whereas those acclimated at 20.5°C were placed directly into 11.5°C water. In each treatment the hemolymph was sampled at times 0, 0.5 h, 1.5 h, 3 h, 6 h, 12 h, 24 h, 48 h and 72 h and on days 5 and 7, respectively.

Statistical Analysis

All statistics were run with SPSS 13.0 software. The normality test was conducted first and showed normal distribution on all the data used in this study. ANOVA and Tukey *b* multiple comparisons were then applied. A probability level of $P < 0.05$ was considered statistically significant.

RESULTS

Gradual Water Temperature Change

The results from the first treatment indicated that a gradual decrease or increase in water temperature from 16°C produced a declining trend in NRR time. When the water temperature was decreased from 16°C to 7°C (Fig. 1A) the NRR time did not change significantly ($P > 0.05$) between 16°C and 15°C . The NRR time then dropped significantly ($P < 0.05$) to $77.78 \pm 8.01 \text{ min}$ at 13°C , and further decreased to $33.33 \pm 3.33 \text{ min}$ on day 10 at 7°C . The NRR time then fluctuated at this level until the end of the experiment. When the water temperature was gradually raised from 16°C to 25°C (Fig. 1B) the NRR time did not change significantly ($P > 0.05$) between 16°C and 17°C . Further water temperature increase from 17°C to 19°C produced a significant decrease in NRR time ($P < 0.05$), dropping from $108.89 \pm 5.88 \text{ min}$ to $76.11 \pm 5.47 \text{ min}$. The NRR time declined to $31.67 \pm 1.67 \text{ min}$ on day 10 at 25°C and then remained at this level until the end of the experiment.

In the second treatment the gradual water temperature change from 7°C or 25°C to 16°C produced an increasing trend in NRR time. When water temperature was increased from 7°C to 16°C (Fig. 2A) the lowest NRR time of $40.0 \pm 2.89 \text{ min}$ was observed on Day 0 at 7°C . The NRR time then increased gradually as the temperature was increased over time. At the temperature of 15°C on day 8 the NRR time reached a level that was not significantly different from the control ($P = 0.352$). The NRR time increased slightly on day 10 once the temperature was changed to 16°C and remained at this level until the end of the experiment. When water

Figure 1. Comparison of NRR times in lysosomes of *H. rubra* with gradual change in temperature: (A) decreasing from 16°C to 7°C, (B) increasing from 16°C to 25°C. Bars express the mean + SE, $n = 9$ abalone. Figures in brackets denote temperature (°C).

Figure 2. Comparison of NRR times in lysosomes of *H. rubra* with gradual change in temperature: (A) increasing from 7°C to 16°C, (B) decreasing from 25°C to 16°C. Bars express the mean + SE, $n = 9$ abalone. Figures in brackets denote temperature (°C).

temperature was decreased from 25°C to 16°C (Fig. 2B) the lowest NRR time of 35.0 ± 2.89 min was observed on day 0 at the temperature of 25°C. The NRR time then increased gradually as the temperature was decreased over time. On day 8 the NRR time was similar to the control ($P = 0.848$) when 17°C was reached. The NRR time further increased slightly at 16°C and remained at this level until the end of the experiment.

During the experimental periods no significant difference in NRR times occurred in the controls in the two treatments ($P > 0.05$).

Rapid Water Temperature Change

In the first treatment when blacklip abalone were transferred directly from 16°C to 7°C or 25°C water a rapid decline in NRR time was produced (Fig. 3). The NRR time dropped significantly ($P < 0.05$) at each sampling time point within the first three to six hours from the initial level of 113.33 ± 3.85 min at 0 h to 50.0 ± 2.89 min at 3 h in the 16°C to 7°C group and to 41.67 ± 1.67 min at 6 h in the 16°C to 25°C group. The NRR time then decreased

slightly to 36.67 ± 3.33 min and 31.67 ± 1.67 at 12 h in these two groups respectively. Statistical analysis showed that from 6 h to the end of the experiment the NRR times in each group did not differ significantly ($P > 0.05$).

In the second treatment when abalone were transferred from 7°C or 25°C to 16°C the NRR times dropped from the initial levels of 40.0 ± 2.89 min and 35.0 ± 2.89 min at 0 h to 30.0 ± 2.89 min and 31.67 ± 1.67 min at 0.5 h, respectively (Fig. 4). From 0.5 h onwards the NRR time gradually increased over time. By 12 h the NRR times for the 7°C to 16°C and 25°C to 16°C groups were 93.33 ± 3.85 min and 93.33 ± 3.85 min, respectively, which was not significantly different ($P > 0.05$) from the controls.

During the experimental periods no significant differences in NRR time occurred in the controls for the first two treatments respectively ($P > 0.05$).

In the third treatment, when the abalone were transferred directly from 7°C to 25°C the NRR time dropped significantly ($P = 0.014$) within the first 3 h from the initial level of 40.0 ± 2.89 min

Figure 3. Comparison of NRR times in lysosomes of *H. rubra* with rapid change in temperature from 16°C to 7°C and 25°C, respectively. Bars express the mean + SE, $n = 9$ abalone.

at 0 h to 20.0 ± 2.88 min at 3 h and decreased further to 16.67 ± 1.67 min at 12 h. From 12 h onwards the NRR time gradually increased to 31.67 ± 1.67 min on day 7 (Fig. 5). When abalone were transferred directly from 25°C to 7°C the NRR time also dropped significantly ($P = 0.022$) within the first 6 h from the initial level of 35.0 ± 2.88 min at 0 h to the lowest level of 18.33 ± 1.67 min at 6 h. From 6 h onwards the NRR time gradually increased to 31.67 ± 4.41 min at 48 h and then fluctuated around this level until the end of the experiment. The mortality levels of the direct temperature changes from 7°C to 25°C and 25°C to 7°C were 24.6% and 17.5% respectively.

In the fourth treatment it was observed that the 11.5°C to 20.5°C temperature change group produced a significant drop ($P < 0.05$) in NRR time from the initial level of 77.78 ± 5.88 min at 0 h to 38.33 ± 4.41 min at 1.5 h. The NRR time then increased gradually over the remaining sampling times, reaching 73.33 ± 3.85 min on day 7 (Fig. 6). In the 20.5°C to 11.5°C temperature change group the NRR time dropped significantly ($P < 0.05$) within the first 0.5 h from the initial level of 73.33 ± 3.85 min at 0 h to 38.33 ± 1.67 min at 0.5 h. From 1.5 h onwards the NRR time increased gradually and reached 66.67 ± 3.85 min on day 7 (Fig. 6). No mortalities were recorded in this treatment.

The Effect of Rapid Versus Gradual Temperature Change on Lysosomal Stability at Final Temperature

Analysis of NRR times at 7°C, 16°C and 25°C indicated that the lysosomal membrane stabilities at these temperatures were not significantly affected by the speed (gradual or rapid) of change of water temperature ($P > 0.05$).

DISCUSSION

When water temperature was changed by 1°C from 16°C in the gradual temperature change experiments the NRR times changed slightly ($P > 0.05$). As water temperature was further changed to lower than 15°C or higher than 17°C a significant drop in the NRR times was produced. These results indicate that temperatures between 15°C and 17°C are optimal for maintaining lysosomal membrane stability in blacklip abalone *H. rubra*. These results are also consistent with the findings in the published studies on this species by using performance and growth rate as indicators. Gilroy and Edwards (1998) found that the preferred temperature for *H. rubra* was 16.9°C and the optimum temperature for their growth was 17°C, which was supported by the finding of Harris et al., in

Figure 6. Comparison of NRR times in lysosomes of *H. rubra* with rapid change in temperature from 11.5°C to 20.5°C and 20.5°C to 11.5°C, respectively. Bars express the mean + SE, $n = 9$ abalone.

2005 that the highest recorded growth for *H. rubra* was at the temperature of 17°C. Harris et al. (2005) also noted that at the temperature of 19°C the growth rate of *H. rubra* was reduced considerably.

The rapid temperature change experiment showed that when abalone were transferred directly from 16°C to 7°C or 25°C water the NRR times dropped to the levels that were not significantly different from those corresponding with 7°C or 25°C temperature within 3–6 h. When abalone were transferred from 7°C or 25°C to 16°C water their NRR times increased to the optimal level within 12 h. These results indicate that when *H. rubra* is subjected to rapid water temperature changes the lysosomal membrane destabilization is quicker than its stabilization. Similar results were also found by Zhang et al. (2006) with the Pacific oyster, *Crassostrea gigas*. In their experiments, when oysters were transferred from 15°C to 5°C or 25°C water, the NRR time decreased to the levels corresponding with 5°C or 25°C water within 3 h, which was substantially less than the five days required in the reverse experiment in which *C. gigas* was transferred from 5°C or 25°C to 15°C.

In the gradual and rapid temperature changes between 7°C and 16°C and between 16°C and 25°C the lowest NRR times were recorded at 7°C and 25°C, suggesting that these temperatures produced the greatest impact on lysosomal stability. However, no mortalities were recorded in these treatments, indicating that *H. rubra* could tolerate temperature changes in these ranges.

When blacklip abalone were subjected to the direct water temperature changes between 7°C and 25°C or 11.5°C and 20.5°C the NRR time decreased to the levels significantly lower than those previously recorded for these temperatures at the acclimation stages. It was also noted that after an initial decrease the NRR time increased to the levels corresponding with 7°C, 11.5°C, 20.5°C or 25°C water gradually, indicating that the lysosomal membrane had the ability to recover from this extra stress. In the between 7°C and 25°C treatments, a mortality level of more than 17.5% and a slower recovery in NRR times were recorded, suggesting that these temperature changes had produced the strongest physiological impact on the abalone in this study.

The differences between the start and the end temperatures were all 9°C in the rapid temperature changes between 7°C and 16°C, 16°C and 25°C and 11.5°C and 20.5°C. However, only the

between 11.5°C and 20.5°C treatments produced the extra stress response, suggesting that different ranges of water temperature change could affect the lysosomal membrane integrity differently.

The results from gradual and rapid water temperature changes between 7°C and 16°C and between 16°C and 25°C showed that in *H. rubra* the lysosomal membrane stability at the final temperatures of 7°C, 16°C, and 25°C were not significantly affected ($P > 0.05$) by the rate (gradual or rapid) the water temperature was changed. A similar phenomenon was found by Zhang et al. (2006) in *C. gigas* at the final temperatures of 5°C, 15°C and 25°C.

In this study a logical correlation between water temperature changes and NRR levels has been established in blacklip abalone, *H. rubra*. In other publications high water temperature has been documented to affect the growth, health and survival in various abalone species (Prince et al. 1987, Winstanley 1972, Steinbeck et al. 1992, Cheng et al. 2004). It is, therefore, reasonable to expect that by using NRR assay as an indicator, the stress induced by temperature changes in some farming practices could be minimized.

Previous studies also showed that the performances such as growth rate of wild abalone were mainly influenced by temperature, food supply and channeling of energy into gonad production (Ino 1952, Sakai 1962, Poore 1972, Shepherd & Hearn 1983). However, these factors are often highly correlated and it is seldom possible to isolate causal effects between the seasonally changing components (Shepherd & Hearn 1983). It is anticipated that if the impacts of these factors could be quantified by a standard method such as the NRR assay used in this study their relative influences on the performances of wild abalone could then be evaluated. Comparison and prediction of abalone performances at different localities and/or seasons would then become possible. The response of NRR times to temperature changes in blacklip abalone has been characterized in this study. Further work is needed to determine the effects from other factors. Investigations with NRR assay on Pacific oysters have showed that starvation, gonad development and spawning could all individually significantly impair the lysosomal membrane stabilities in blood cells, thus imposing stresses on animals (Cho & Jeong 2005, Zhang & Li 2006, Song et al. submitted).

GROWTH AND DEVELOPMENT OF VEINED RAPA WHELK *RAPANA VENOSA* VELIGERS

JULIANA M. HARDING

Department of Fisheries Science, Virginia Institute of Marine Science, P. O. Box 1346,
Gloucester Point, Virginia 23062

ABSTRACT Planktonic larvae of benthic fauna that can grow quickly in the plankton and reduce their larval period duration lessen their exposure to pelagic predators and reduce the potential for advection away from suitable habitats. Veined rapa whelks (*Rapana venosa*, Muricidae) lay egg masses that release planktonic veliger larvae from May through August in Chesapeake Bay, USA. Two groups of veliger larvae hatched from egg masses during June and August 2000 were cultured in the laboratory. Egg mass incubation time (time from deposition to hatch) ranged from 18–26 d at water temperatures between 22°C and 27°C. Four stages of rapa whelk veliger development along a time series from hatch to settlement were described using external morphological features. Rapa whelk veligers were measured at three-day intervals from hatching through the onset of spontaneous settlement. A four-parameter Gompertz growth model was used with length at age data from cultures of rapa whelk veligers to estimate maximum growth rates for June and August hatched groups. Larval rapa whelks settled at shell lengths of 1.18–1.24 mm after planktonic larval periods ranging from 24–42 d. Maximum larval growth rates observed in August (0.03 mm d^{-1}) are 50% lower than maximum larval growth rates observed for June hatched rapa whelk veligers (0.071 mm d^{-1}). Daily larval growth rates from hatch to first spontaneous settlement for rapa whelk veligers ranged from 0.002 – 0.099 mm d^{-1} with maximum growth rates occurring between 12–18 d post hatch in June. Larval period duration, or the time from hatch to first spontaneous settlement, was 12 days shorter for June hatched larvae than for August hatched larvae. Water temperature was not significantly correlated with larval growth rates (mm d^{-1}) in either June or August. Plasticity in larval period duration may enhance survival and dispersal opportunities for planktonic rapa whelk veligers.

KEY WORDS: veined rapa whelk, *Rapana venosa*, veliger, plankton, larval growth rate, propagule pressure, Muricid, gastropod

INTRODUCTION

Many benthic invertebrates rely on planktotrophic development of larval forms as part of their life history strategies. Although planktonic larvae are vulnerable to pelagic predators and advection away from suitable habitats (Crisp 1974), planktonic development is a means to avoid benthic predators immediately after emerging from egg capsules and provides a mechanism for genetic exchange and dispersal (Scheltema 1971). Larvae with faster growth rates reduce their exposure to planktonic predators and dispersal vectors and potentially increase the number of larvae that survive to settlement. At the end of planktonic development, larvae settle to the benthos and spontaneously metamorphose losing specialized swimming structures in the process. The transition from pelagic to benthic lifestyle may be delayed in marine gastropods and the length of this delay may be related to the rate of larval development in the plankton (Pechenik 1980, Pechenik & Lima 1984), the presence of suitable settlement habitat (Crisp 1974, Pechenik 1980), and, in the case of larvae that use particular benthic prey, the presence of suitable prey items at settlement sites (Crisp 1974, Pawlik 1992, Davis & Stoner 1994).

Veined rapa whelks (*Rapana venosa*) are a recent addition to Chesapeake Bay's gastropod fauna. Native to Japanese and Korean waters, rapa whelk adults and egg masses were collected from Chesapeake Bay, USA in 1998 (Harding & Mann 1999). Native channeled whelks (*Busycotypus canaliculatus*), knobbed whelks (*Busycon carica*), Atlantic oyster drills (*Urosalpinx cinerea*) and Thick-lipped oyster drills (*Eupleura caudata*) all lay egg masses, which release fully developed juvenile snails that walk out of egg cases and begin benthic residence. In contrast, adult rapa whelks lay egg masses that release swimming veliger larvae, which develop in the plankton for 3–4 wk (Harding & Mann 2001) before eventually settling onto hard substrates, undergoing metamorphosis and taking up residence in the benthos. The period of plank-

tonic larval development may facilitate rapa whelk genetic exchange and dispersal into new habitats while reducing exposure to benthic predators prior to metamorphosis. The presence of a planktonic larval stage has enabled rapa whelk larvae to be moved across natural zoogeographic boundaries in ballast water of commercial ships and, within an estuary, may enhance dispersal and survival to recruitment with the end product being a net increase in propagule pressure, the rate at which breeding individuals are recruited to the population (Williamson 1996), and increased colonization success. The objectives of this study are to qualitatively describe rapa whelk veligers throughout their period of planktonic development and quantitatively describe growth rates of cultured rapa whelk larvae.

MATERIALS AND METHODS

Egg Mass Sources and Culture

Adult rapa whelk broodstock were held in flow-through systems at ambient temperature and salinity conditions in the lower York River, Gloucester Point, Virginia with food (hard clams (*Mercenaria mercenaria*) and oysters (*Crassostrea virginica*), Harding & Mann 1999) available in excess.

During 2000, a subset of the egg masses produced by the broodstock populations in June and July were set aside for larval culture and description of larval development. Immediately after removal from the broodstock tanks, each egg mass destined for larval culture was placed in an individual container with 1 L of 5- μm filtered seawater. The water in egg mass culture beakers was changed every other day. Egg mass incubation time (time from deposition to hatch or release of swimming veliger larvae) at ambient York River, Virginia conditions was recorded for each egg mass.

Veliger Culture

Egg masses that hatched on June 21 and 23 and August 1, 2000 provided rapa whelk veligers for descriptions of larval develop-

E-mail: jharding@vims.edu

ment and growth. After hatching or release of swimming veliger larvae from an egg mass, rapa whelk veligers were filtered from egg mass culture water using 80 μm Nytex sieves and cultured in aerated filtered (5 μm) seawater (15–22 ppt) at temperatures of 25°C to 29°C and densities of <700 veligers L^{-1} . Veligers were fed a mixed algal diet (*Pseudoisochrysis* sp., *Chaetoceros* sp., *Tetraselmis* sp.) every other day and were maintained at 10 h dark/14 h light conditions.

Observations on Larval Development and Measurements of Larval Growth

A minimum of nine individual veliger larvae were removed from cultures and narcotized with a 7.5% magnesium chloride/seawater solution every three days from hatch (day 0) through the date of first natural spontaneous settlement of veligers within cultures. When veligers were sufficiently narcotized to stop swimming and rest on the bottom of the dish with vela extended and filtering, individual veligers were examined under a dissecting microscope to verify that they were alive and photographed with an image analysis system. After image capture, veligers were placed in 100% filtered seawater (equivalent to larval culture water), examined to verify that the effects of magnesium chloride had worn off, and returned to their original larval culture. Measurements of veliger shell length (SL, distance from the tip of the spire to the end of the siphonal canal to the nearest 0.001 mm) were made from the digital images using an image analysis system.

Data Analyses

Significance levels for all analyses were established *a priori* at $P = 0.05$. Assumptions of homogeneity of variance were tested with Bartlett tests and assumptions of normality were tested using the Ryan-Joiner test for normality.

Larval culture water temperatures from day of hatch to day of first spontaneous settlement for June and August hatched cultures were compared using a 1-way ANOVA with month of hatch as a factor. Temperature data satisfied assumptions of normality and homogeneity of variance without transformation.

Four parameter Gompertz models were used to describe rapa whelk larval growth in terms of shell length (mm) at age (d) data for presettlement and settlement stage rapa whelk veligers hatched in June and August using the equation:

$$L = L_0 + a e^{-e^{-\left(\frac{t-t_0}{b}\right)}}$$

where L_0 is the veliger shell length (mm) at hatch or $t = 0$, t is time posthatch or age in days, t_0 is the time corresponding to the midpoint of the rise, a is the maximum attainable larval size, and b is a rate constant. Maximum growth rate during the larval period was calculated using the equation:

$$\text{Maximum growth rate (mm d}^{-1}\text{)} = 0.368 \left(\frac{a}{b}\right)$$

The Gompertz model has previously been used to describe molluscan growth on a length at age basis (Devillers et al. 1998, Chicharo & Chicharo 2000, Rodriguez et al. 2001). The four-parameter model was used because it incorporates larval size at hatching from the egg cases.

Larval growth rates at intervals during larval development were estimated for three-day intervals between measurements using the formula:

$$\text{growth rate (mm d}^{-1}\text{)} = \frac{\text{Average shell length (mm)}_{t+3d} - \text{Average shell length (mm)}_t}{3 d}$$

where t is the time post hatch or age in days. Average shell lengths were used because veliger growth rates were measured sequentially as groups randomly chosen from cultures instead of following individual veliger larvae for the duration of planktonic development. Linear regression analyses were used to evaluate the relationship between daily larval growth rate (mm) and water temperature (°C).

RESULTS

In 2000, egg mass deposition in rapa whelk broodstock tanks began on May 15 and continued through August 15. Egg masses hatched June 21 through 23 were deposited between May 15 and June 6 with an average incubation time of 26.3 ± 2.3 d (standard error) at average water temperatures of $22.6^\circ\text{C} \pm 0.31^\circ\text{C}$. Egg masses hatched August 1 were deposited on July 14 with an incubation time of 18 d at average water temperatures of $27.2^\circ\text{C} \pm 0.18^\circ\text{C}$. Chung et al. (1993) describe an incubation period of 17 d from deposition to hatch for rapa whelk egg cases from Korean waters in the laboratory at water temperatures of 18.3°C to 20.4°C .

For descriptive purposes, rapa whelk veligers along the continuum of development were assigned to one of four groups on the basis of visible morphological features. Davis et al. (1993) used a similar development scheme for three species of *Strombus* larvae. All references to age in days use the hatch date (0 d) as a starting point and are thus days-post hatch. Pictures of larval rapa whelk veligers are presented for all four developmental stages in Figure 1.

Stage I rapa whelk veligers (0–5 d) had a bilobed velum, a translucent foot and visible eye stalks (Fig. 1A). Their brown shells were smoothly rounded at the spire (Fig. 1A) with the development of the first whorl beginning 5–6 d post hatch. The beak and columella were visible at hatch and grew quickly, often presenting an almost translucent shell layer that gradually darkened with age (Fig. 1A, B). The beating heart was clearly visible through the shell at hatch. Two rows of cilia were visible along the outer edge of the velar lobes after 2 d (Fig. 1B). Veliger shell length at hatch estimates were between 0.406 (June) and 0.412 (August) mm (Table 1). Actual shell measurements were not made on veligers at hatch (0 d) because the rounded shell morphology made it impossible to position specimens (narcotized or not) on a single level plane under the microscope for image capture.

Stage II veligers (6–9 d) had an elongated beak, a four lobed velum with approximately proportionate lobes, and a relatively small opaque foot (Fig. 1C,D). By 6 d, one complete body whorl and shell shoulder were present (Fig. 1C) and the spiral line on the body whorl left by the presuture of the beak was obvious. Antennae were visible posterior to the eyestalks at day 9 (Fig. 1D).

Stage III veligers (10–23 d) continued to have an elongated beak with a suture in the middle and a proportionate four lobed velum but the foot was white and muscular with visible muscular contractions and greatly increased range of mobility (Fig. 1E,F). During Stage III, the foot began to have distinguishable anterior and posterior regions and became spade shaped. The operculum was clearly visible by 18 d. At 12–15 d, the larval shell was dark brown with two prominent shell shoulders, a well-developed col-

Figure 1. Pictures of rapa whelk (*Rapana venosa*) veligers in Stage I (A: 2-d-old veliger, B: 5-d-old veliger), Stage II (C: 6-d-old veliger, D: 9-d-old veliger), Stage III (E: 12-d-old veliger, F: 15-d-old veliger) and Stage IV (G: 38-d-old veliger, H: 23-d-old veliger). The scale bar in each picture represents 1 mm. Morphological features are noted, including the antenna (a), shell beak (b), columella (c), eye stalks (e), foot (f), mouth (m) operculum (o), siphonal canal (sc), first shell shoulder (ssh1), second shell shoulder (ssh2), spire (s) and velum (v).

TABLE 1.

Model coefficients for four parameter Gompertz regressions used to describe rapa whelk larval growth with standard error estimates for model coefficients in parentheses.

Hatch month	a	b	t_0	L_0	Model R^2
June	0.869 (0.044)	4.478 (0.538)	13.963 (0.376)	0.406 (0.023)	0.88
August	1.139 (0.153)	12.258 (1.967)	29.826 (1.718)	0.412 (0.014)	0.86

umella and siphonal canal, and visible rounded bumps/dimples on the exterior shell surface (Fig. 1E). By 18–21 d, a third shell shoulder was visible.

Stage IV veligers (24 d-settlement) had a prominent siphon that was typically extended from the siphonal canal and a four lobed velum where the anterior lobes were slightly larger than the posterior lobes (Fig. 1G,H). Veligers were competent to settle from 24 d forward, with size at settlement ranging from $1.18 \pm \text{SE } 0.03$ mm (August) to 1.24 ± 0.03 mm (June). By 27 d, three complete shell whorls were present with three distinct shell shoulders. All four lobes of the velum began elongating at 30 d becoming almost finger-like by 33 d. The foot continued to grow and became spade shaped (Fig. 1G,H). As the veligers aged, the beak gradually become less elongate and by 30 d was recognizable as only a simple point in swimming veligers. By 30 d, veligers spent at least half of the time with their velum retracted and the foot extended and probing available hard surfaces. At settlement, the shell was dark brown/black and the operculum had grown to the same size as the opercular opening and had dark brown/black edges with a light brown center.

Veligers hatched in June began settling at 24 d with all June cultures achieving settlement by 30 d. Veligers from all three August hatched cultures settled at 42 d. Larval culture water temperatures for June and August hatched animals were not significantly different (ANOVA, $F = 0.65$, $P = 0.42$).

Larval shell lengths increased rapidly between 9 and 21 d (Fig. 2A) for June hatched veligers. This time window corresponds developmentally and morphologically to Stage III when veligers had a 4-lobed velum, developing foot, and the shell attained its second shoulder or whorl (see earlier). Shell lengths for August hatched veligers increased more slowly throughout larval life (Fig. 3A) and August hatched veligers took 12 d longer to settle than June hatched veligers.

Maximum growth rates for June hatched veligers (0.071 mm d^{-1}) were twice as high as maximum growth rates observed for August hatched veligers (0.033 mm d^{-1}). Estimated daily larval growth rates from hatch to first spontaneous settlement for rapa whelk veligers ranged from 0.002 – 0.099 mm day^{-1} and were generally higher during Stages I through III for June hatched veligers than for August hatched veligers (Fig. 2B and 3B). August hatched veligers were in Stage IV for longer than June hatched veligers and experienced higher relative growth rates than June hatched veligers at 24 and 27 d in Stage IV (Fig. 2B and 3B). It should be noted, however, that all June hatched veligers had settled by 30 d post hatch, whereas August hatched veligers did not settle until 42 d post hatch.

Larval culture water temperatures from June 21 and 23 (hatch dates) through July 15 (date of first settlement) ranged from 25.1°C to 27.9°C with a mean of 26.6°C (standard error $\pm 0.17^\circ\text{C}$) with residual water temperatures typically within 1 degree of the mean (Fig. 2C). Larval culture water temperatures from August 1

(hatch date) through September 11 (42 d, date of settlement) ranged from 25.3°C to 28.3°C with a mean of 26.6°C (standard error $\pm 0.18^\circ\text{C}$) with residual water temperatures up to 1.5°C of the mean (Fig. 3C). Water temperature was not significantly correlated with larval growth rates (mm d^{-1}) in either June ($\text{df} = 1$, $F = 0.43$, $P = 0.52$) or August ($\text{df} = 1$, $F = 0.10$, $P = 0.75$).

DISCUSSION

Larval rapa whelks settled at shell lengths of 1.18 – 1.24 mm after planktonic larval periods ranging from 24–42 d. Maximum larval growth rates observed in August (0.03 mm d^{-1}) are 50% lower than maximum larval growth rates observed for June hatched rapa whelk veligers (0.071 mm d^{-1}). Dobberteen and Pechenik (1987) observed growth rates of 0.027 mm d^{-1} for 0–28 d old *Thais haemastoma canaliculata* maintained at 24°C in labo-

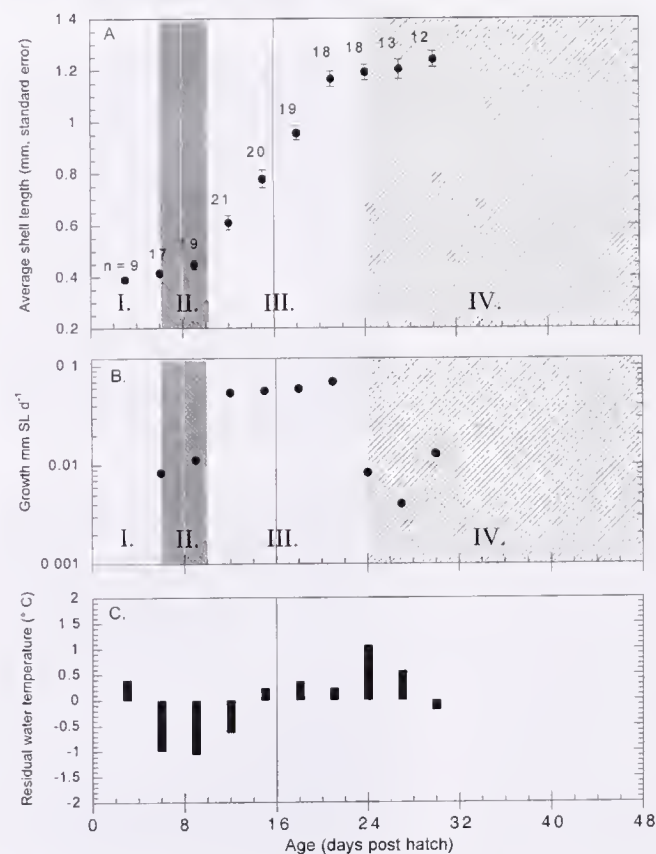

Figure 2. June hatched rapa whelk veliger (A) shell length (mm) at age (d) relationship, (B) growth rate (mm shell length d^{-1}) through planktonic development and (C) larval culture water temperature residuals ($^\circ\text{C}$) from the average larval culture water temperatures from hatch through 30 d.

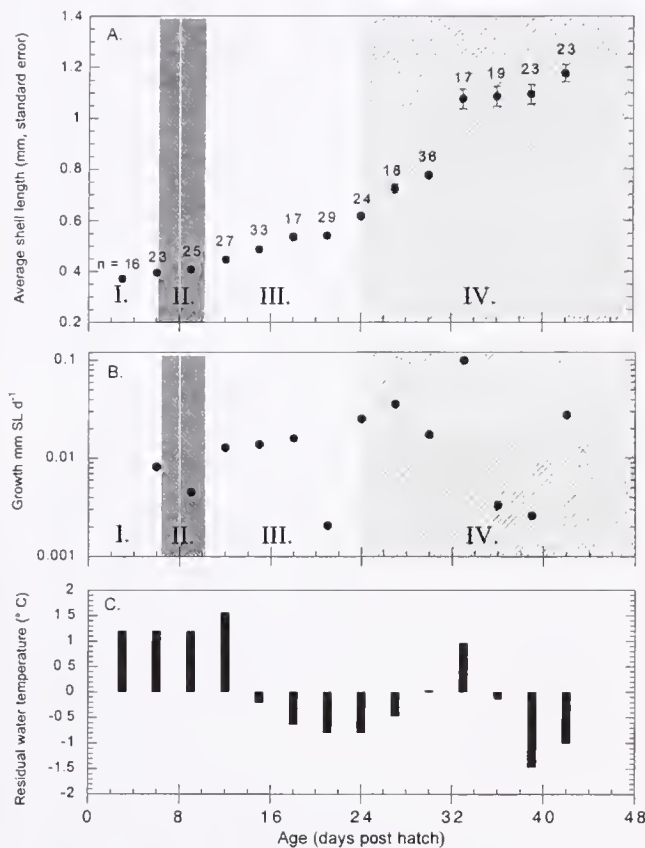

Figure 3. August hatched rapa whelk veliger (A) shell length (mm) at age (d) relationship, (B) growth rate (mm shell length d⁻¹) through planktonic development, and (C) larval culture water temperature residuals (°C) from the average larval culture water temperatures from hatch through 42 d.

ratory cultures. Daily larval growth rates from hatch to first spontaneous settlement for rapa whelk veligers ranged from 0.002–0.099 mm d⁻¹ with maximum growth rates occurring between 12–18 d post hatch in June. The differences in daily growth rates observed through development (this study) may explain the reductions in rapa whelk veliger survivorship and salinity tolerance observed by Mann and Harding (2003) at 12–18 d post hatch. The Stage III period in larval development is probably physiologically stressful because of the observed rapid shell growth. June hatched veligers approximately doubled their shell lengths during Stage III (12 d, 0.447 mm; 18 d, 0.958 mm). This trend was less noticeable for August hatched veligers whose overall growth rates were slower and settlement sizes were smaller.

Observed differences in growth rates and size at settlement between June and August hatched veligers may be related to culture conditions, parental physiological condition as expressed in the egg mass, or these differences may simply reflect a range of developmental plasticity within the species. Although average culture water temperatures (26.6°C) were the same for June and August larval periods, culture water temperatures were 1–2°C above average in early August for the first 6–9 d of larval development. Thermal tolerances of rapa whelk veligers are unknown, but slower growth rates early in larval life may have been related to thermal stress caused by warmer water temperatures. Rapa whelks lay multiple egg masses within a single breeding season (Chung et al. 1993, Harding & Mann 1999). In Chesapeake Bay, rapa whelks

begin laying eggs in May and egg laying continues through August (Mann & Harding 2003). The egg masses used herein were laid from mid-May to early June (June hatch) at the beginning of the adult egg mass laying period and mid-July (August hatch) towards the end of egg mass laying activity. Seasonal decreases in reproductive investment (as indicated by egg size or number per egg mass) have been documented for a marine polychaete (Qian & Chia 1992) and other marine molluscs (Ito 1997) with trends in decreasing number of eggs per clutch (egg mass) and egg size from the beginning to the end of the breeding season related to parental physiology and/or nutritional state. The egg masses used in this study were from multiple wild caught females. Information on adult condition before or at egg laying was not available. The position of each egg mass cultured for this study in the sequence of egg masses produced by each female in this breeding season is also unknown.

One of the most vulnerable portions of the rapa whelk life cycle is the period of planktonic larval development. Larvae that grow quickly in the plankton and reach competence quickly, reduce their exposure to planktonic sources of mortality. Relatively large size at competence increases postsettlement survivorship. Average rapa whelk shell length at settlement (1.18–1.24 mm) is similar to reported size at settlement for other gastropod larvae including *Thais kieneri* (1.04 mm, Middlefart 1996), *Strombina* (*Thais*) *haemastoma* (0.800 mm, Butler 1954), and *Strombus gigas* (1.170 mm, Davis et al. 1993). However, *R. venosa* size at settlement is approximately twice that of *Rapana rapiformis* (0.520–0.540 mm, Ramesh 1999) although both metamorphose and settle as early as 24 d post hatch (*R. rapiformis*, Ramesh 1999; *R. venosa*, this study). Moran (1999) predicts a positive relationship between growth, survivorship and size at settlement for intertidal gastropods. Large size at settlement brings with it increased resistance to starvation (Moran 1999) and reduced vulnerability to benthic predators (Spight 1976, Gosselin 1997).

The observed differences in larval growth rates and larval period duration may affect recruitment success of individual animals and invasion potential of the species as a whole. Animals that settle early in the year will be exposed to a longer growing season during their first year and, as a consequence, reach sexual maturity more quickly than animals that settle later in the year. From the standpoint of biological invasions, animals that grow rapidly to reproductive maturity increase the propagule pressure (Williamson 1996) within a habitat. The observed plasticity in rapa whelk growth rate and larval period duration resulting in successful settlement directly relates to the potential viability of larvae entrained and transported in ballast water as well as the survival of these larvae after introduction into new habitats. This plasticity may explain, at least to some degree, the continued success of rapa whelk invasions into new habitats. Recent invasions by rapa whelks include the Rio de la Plata, Uruguay and Argentina (Pastorino et al. 2000) and the Scheveningen, Netherlands (Vink et al. 2005). Historically, large long-lived gastropods like rapa whelks were not among the candidate fauna for anthropogenic transport to other habitats (Carlton 1999) and geographic range expansion by these benthic infauna relied on slow progression of individuals crawling into new areas or dispersal of planktonic larvae by water currents within the established range of ecological tolerances. Modern reliance on ballast water as part of commercial shipping offers a rapid vector for dispersal of the larval forms of these large predatory gastropods that supercedes natural zoogeographic boundaries and results in deposition of larval forms that have

evolved under one set of ecological and environmental constraints into new habitats lacking these traditional controls.

ACKNOWLEDGMENTS

The author thanks all of the local citizens, watermen, and seafood processors that have donated adult *Rapana* to our research program. P. Crewe, K. Farnsworth, S. Goodbred, C. Goodbred, R. Mann, M. Mann, K. Mann, M. Southworth, and C. Tomlinson assisted with local whelk collection. D. Dolittle, R. Howlett, D. Jones, D. Kerstetter, P. Kingsley-Smith, R. Mann, D. Savini, M. Southworth, C. Ware, and E. Westcott provided assistance with larval culture. D. Findley, D. Sennett and A. Arseniu of the

Virginia Institute of Marine Science Aquaculture Breeding and Technology Center supplied algae for larval cultures. D. Dolittle, R. Howlett, D. Kerstetter, and C. Ware helped with image acquisition, laboratory measurements, and data entry. D. Evans provided statistical advice. R. Mann and M. Southworth provided valuable comments on earlier drafts of this manuscript. Support for this project was provided by the NOAA/National Sea Grant Aquatic Nuisance Species Research and Outreach Program (NA96RG0025/5-29456), Virginia Sea Grant (R/MG-98-3), and the Virginia Institute of Marine Science Department of Fisheries Science. This is Contribution number 2753 from the Virginia Institute of Marine Science.

GASTROPOD ABUNDANCE AND BIOMASS RELATIONSHIPS WITH SALT MARSH VEGETATION WITHIN OCEAN-DOMINATED SOUTH CAROLINA, USA ESTUARIES

JOHN J. HUTCHENS, JR.^{1*} AND KEITH WALTERS²

¹Department of Biology, Coastal Carolina University, PO Box 261954, Conway, South Carolina 29528 and ²Department of Marine Science, Coastal Carolina University, PO Box 261954, Conway, South Carolina 29528

ABSTRACT Molluscs, both gastropods and bivalves, appear to disproportionately influence the dynamics of salt marsh habitats. Bivalves typically are facilitators positively affecting the growth and survival of marshes, but gastropods may have unanticipated top-down effects through direct consumption of the predominant marsh vegetation, *Spartina alterniflora*. Natural, elevational differences in *S. alterniflora* density and morphology also may exert an influence on the spatial distributions of marsh snails. We examined the abundance of both plants and snails across an elevation gradient to determine if similarities or differences existed in the observed distribution patterns. Plant, mainly *S. alterniflora*, and snail, *Littoraria irrorata* (Say) and *Melampus bidentatus* Say, densities were measured along tidal creek to forest transects within the intertidal marshes of three marine-dominated South Carolina inlets. Significant differences in *S. alterniflora* density among marsh zones were paralleled by similar *L. irrorata* density differences. A consistent, unimodal pattern with peak *L. irrorata* density in the “short,” dense *S. alterniflora* mid marsh occurred within each inlet. In contrast, *M. bidentatus* was restricted almost entirely to the high marsh across all transects and inlets. Densities of *L. irrorata* and *S. alterniflora* were positively correlated in the low marsh consistent with the potential importance of culms as a food source and refuge from predators. *Littoraria irrorata* biomass was significantly different among zones in only one inlet and increased in a shoreward direction in two inlets. Although biomass patterns previously have not been reported for Southeastern US marshes, amounts were consistently greater than expected within the high-marsh zone. In SC, *L. irrorata* appears to be a conspicuous resident across the entire vegetated marsh and our results suggest previous studies focusing on the marsh near tidal creeks could underestimate appreciably the total population and overall significance of *L. irrorata* within coastal marshes.

KEY WORDS: *Littoraria irrorata* (Say), *Melampus bidentatus* Say, *Spartina alterniflora*, marsh zonation, snail biomass

INTRODUCTION

Molluscs, both gastropods and bivalves, appear to influence disproportionately the dynamics of salt marsh habitats. Bivalves often are characterized as facilitators positively affecting the growth and survival of marshes either directly (Bertness 1984) or indirectly (Meyer et al. 1997, Dame et al. 2001). Early evidence suggested resident gastropods had limited to no direct effects on the salt marsh and primarily were involved in the recycling of detritus (Odum & Smalley 1959, Teal 1962, Stiven & Kuenzler 1979). However, recent studies indicate one of the common snail species, *Littoraria irrorata* (Say), has unanticipated top-down effects on the predominant marsh vegetation, *Spartina alterniflora* (Silliman & Zieman 2001, Silliman & Bertness 2002, Silliman et al. 2005).

The extent of potential gastropod effects on salt marsh environments ultimately will depend on the natural abundance and distribution of the various floral and faunal species. In Southeastern US marshes conspicuous plant zonation (see Chapman 1974) results from the interplay between physical tolerance to tidal inundation at lower elevations and interspecific competition at higher elevations (Pennings et al. 2005). Macrofaunal zonation patterns within marshes are less transparent (see however Kneib 1984, Netto & Lana 1997, Richardson et al. 1998, Angradi et al. 2001) with no accepted paradigm to explain observed patterns (Kneib 1984, Levin & Talley 2000). Ecological explanations for gastropod zonation in salt marshes could parallel paradigms established in the rocky intertidal (e.g., Connell 1961a, 1961b, Paine 1969). A result would be an overlap in the peak distribution of a possible keystone species, *L. irrorata*, and the maximum production of its primary food and habitat resource, *S. alterniflora*. To

establish if an overlap exists, we documented the zonation patterns of *S. alterniflora* and the two predominant gastropod species, *L. irrorata* and *Melampus bidentatus* Say, within three South Carolina inlets.

Littoraria irrorata and *M. bidentatus* are both common in western Atlantic salt marshes, but *L. irrorata* typically is reported from monospecific stands of *S. alterniflora* (e.g., Smalley 1959, Crist & Banta 1983). *M. bidentatus* is found in greater densities within the more speciose high marsh (Kerwin 1972, Fell et al. 1991). However, density, size and biomass have not been shown to vary in a consistent manner across the marsh for either species. Factors that may affect snail abundance along a tidal elevation gradient also have been implicated in affecting gastropod size distributions. Vermeij (1972) proposed intertidal gastropods would exhibit one of two possible patterns attributed to either predation or desiccation effects: Type 1 or a shoreward increase in size because larger snails are better able to resist desiccation and Type 2 or a decrease in size over the same gradient, because larger individuals would be less susceptible to aquatic predators. Littorinids in the rocky intertidal primarily exhibit a Type 2 pattern suggesting a response to predation pressure (Vermeij 1972). In saltmarshes, blue crab (*Callinectes sapidus*) predation on *L. irrorata* also decreases with increasing distance away from tidal creeks (Schindler et al. 1994, Lewis & Eby 2002). Although results from Schindler et al. (1994) and Lewis & Eby (2002) suggest *L. irrorata* should exhibit a Type 2 pattern, snail sizes have been shown to exhibit both Type 1 and 2 patterns (Hamilton 1978, Crist & Banta 1983). To indirectly examine the possible effects of desiccation and predation on salt marsh snails we measured all snail shell lengths to test whether saltmarsh snails conformed to either of Vermeij's (1972) hypothesized size distribution patterns.

Differences in snail abundance, size and biomass along a tidal elevation gradient in three ocean-dominated Southeastern marshes

*Corresponding author. E-mail: jhutch@coastal.edu

were examined to test whether physical or biological factors contributed to observed zonation patterns. Specifically, we hypothesized that *L. irrorata* density, biomass and mean length would vary in concert with vegetation zones because of a suspected dependence on *S. alterniflora* for food (Silliman & Bertness 2002, Silliman & Newell 2003) and increased aquatic predation in the low marsh (West & Williams 1986, Schindler et al. 1994, Lewis & Eby 2002). We also expected that *M. bidentatus*, given its small size, thin shell and pulmonate physiology would be more abundant in the mixed vegetation of the high marsh where desiccation and not predation would contribute most to the zonation pattern. Specifically, we set out to: (1) examine if *L. irrorata* and *M. bidentatus* exhibited distinct zonation patterns within southeastern US marshes; (2) evaluate existing size-frequency distributions to gain insights into possible mechanisms influencing salt marsh snail distributions and (3) examine if any relationship existed between the density and biomass of *L. irrorata* and the density of *S. alterniflora* stems.

MATERIALS AND METHODS

Study Site

Salt marshes in three ocean-dominated inlets along the northern South Carolina coast were selected for study: Hog, Murrells and North Inlets. Hog Inlet forms the southern boundary for Wailes Island (33°50'43"N, 78°35'12"W), a 0.5 × 4.0-km undeveloped barrier island. Study sites were in the extensive lagoonal marshes that exist along the backside of Wailes Island. Murrells and North Inlets have been studied extensively (e.g., Vernberg et al. 1992) but differ in residential development of the local watershed. Murrells Inlet, ca. 62 km south of Hog Inlet, has considerable shoreline and upland development although Huntington Beach State Park protects much of the southern portion of the Inlet. A study site within the mainland marshes just north of the park boundary near public oyster reefs was selected (33°31'17"N, 79°03'53"W). North Inlet is 31 km south of Murrells Inlet, and it is the site of the Baruch Marine Institute. The inlet and marshes are protected as part of the National Estuarine Research Reserve (NERR) system but a few residences and a golf course are located on the northern edge. Mainland study sites within North Inlet marshes were at Oyster Landing (33°31'04"N, 79°11'32"W) and Clambank (33°20'09"N, 79°11'36"W), two extensively studied sites (e.g., Morris & Haskin 1990).

Sampling Design

To assess the spatial distribution of snails within the intertidal marshes without having to account for temporal differences, all samples were collected within a relatively short May to June period in 2003. The sampling period likely represents the time of greater snail density just after spring juvenile settlement and before increased summer mortality (KW, pers. obs.). Hog, North and Murrells Inlets were sampled three, two and one times respectively over the 2 mo. Snails were sampled along an approximate transect between tidal creek and forested upland uniquely established at each site on each date. A total of 5–20 samples from 0.25 m² quadrats placed along each transect within each of three vegetated zones was sampled. The low-marsh zone was identified by the presence of a monoculture of "tall" (>1 m) *S. alterniflora*. The short-form, <0.5-m tall, of *S. alterniflora* characterized the mid-

Figure 1. Mean (± 1 SE) density of the total number of *Spartina alterniflora* stems in low-, mid and high-marsh zones of salt marshes in Hog Inlet (A), North Inlet (B) and Murrells Inlet (C). Different lower-case letters represent significant differences among zones.

marsh zone. Dense areas of *Spartina patens*, *Distichlis spicata* and *Juncus roemerianus* and the less common *Borrichia frutescens* and *S. alterniflora* identified the high-marsh zone at each site.

All snails within each quadrat were collected, returned to the laboratory and frozen at -20°C for later counting, measurement and biomass estimation (see later). On the first sampling date, May 2, 2003, snails were counted and not collected; biomass was not estimated. The total number of *S. alterniflora* stems >10 cm tall was also counted from a haphazardly chosen corner ($0.25 \text{ m} \times 0.25 \text{ m}$) of each quadrat.

Laboratory Analyses

Snail biomass was estimated by measuring individual shell lengths and applying a length-mass regression for each species. Shell length was measured from the spire apex to aperture tip to the nearest 0.1 mm with digital calipers. To establish species' length-mass regressions shell length and tissue mass (without shell) were measured for a subset of snails collected from Hog Inlet sites ($n = 184$ for *L. irrorata*, $n = 56$ for *M. bidentatus*). Tissue was dissected from individual shells, dried to constant mass at 60°C , and ashed at 500°C for >4 h in a muffle furnace to determine the ash-free dry mass (AFDM). A power curve was fit to the data for each species using nonlinear regressions in Sigma-Plot (Vers. 8.0, SPSS, Inc.).

Statistical Analyses

Statistical differences ($\alpha = 0.05$) among marsh zones and transects within inlets were assessed using analysis of variance (ANOVA) on $\log_{10}(x + 1)$ -transformed values. Separate ANOVAs were conducted for each inlet using the General Linear Model procedure in SYSTAT (Vers. 10.0, SPSS, Inc.). Significant main effects were followed by Tukey HSD *post hoc* test to assess differences among levels (i.e., low-, mid and high-marsh zones). Any potential relationship between *L. irrorata* and *S. alterniflora* densities ($\log_{10}(x + 1)$ -transformed) were examined with Pearson's Product-Moment correlation. The correlation between *L. irrorata* and *S. alterniflora* densities was calculated separately for each marsh zone using data from all inlets combined to assess overall relationships across inlets. *Melampus bidentatus* and *S. alterniflora* correlations were not considered because the distribution of *M. bidentatus* was restricted to the high marsh where little *S. alterniflora* was present.

The fit of *L. irrorata* to a Type 1 or Type 2 model (*sensu*

Vermeij 1972) within each inlet was tested by graphically examining the mean length of *L. irrorata* with respect to marsh zone. Juvenile snails <5 mm were omitted from the analysis because individuals were typically found inside *S. alterniflora* leaf culms and likely were less susceptible to predation (Crist & Banta 1983).

RESULTS

A significant power relationship between shell length and tissue AFDM was identified from the Hog Inlet subsample of both *L. irrorata* (tissue mass = $0.0080 \times \text{length}^{3.1157}$, $P < 0.0001$, $R^2 = 0.928$) and *M. bidentatus* (tissue mass = $0.0077 \times \text{length}^{2.4351}$, $P < 0.0001$, $R^2 = 0.930$). Snail biomass differences among zones and transects were estimated using these equations.

Spartina alterniflora stem densities in each inlet marsh exhibited a similar pattern: mid $>$ low $>$ high marsh (Fig. 1). Significant stem density differences existed among zones in each inlet, but they differed only among transects in Hog Inlet (Table 1). Stem density was always significantly lowest in the high marsh (Fig. 1).

Littoraria irrorata density was significantly different among marsh zones in each inlet (Table 1), and showed a similar overall pattern as *Spartina* density in each respective inlet (Fig. 1 and Fig. 2). *Littoraria* density was significantly less in the high marshes of North and Murrells Inlets, and significantly greater in the mid marsh of Hog Inlet (Fig. 2). In contrast, biomass of *Littoraria* was only significantly different among zones in Murrells Inlet (Table 1), where it was significantly less in the low marsh (Fig. 2). Furthermore, biomass tended to increase from low to high marsh in North and Murrells Inlets (Fig. 2). No significant differences in density or biomass of *L. irrorata* were found among transects in any inlet (Table 1).

In each inlet the distribution of *M. bidentatus* primarily was restricted to the high marsh (Fig. 3) and resulted in significantly greater density and biomass in the high marsh zone (Table 1, Fig. 3). Densities were also significantly different among transects at Hog Inlet (Table 1).

Littoraria irrorata density was positively correlated with *S. alterniflora* stem density for low- ($P = 0.008$, $R = 0.423$) but not mid or high-marsh zones ($P > 0.05$).

The shell length of *L. irrorata* increased in a shoreward direction (Type 1 pattern) in both Murrells and North Inlets (Fig. 4). However, there was no obvious pattern in *L. irrorata* shell size at Hog Inlet (Fig. 4).

TABLE 1.

DISCUSSION

Significant differences in *S. alterniflora* density among marsh zones were paralleled by similar *L. irrorata* density differences. The same zonation pattern (mid > low > high marsh) in *S. alterniflora* stem densities occurred in each inlet and is common for western Atlantic salt marshes (e.g., Valiela et al. 1978, West & Williams 1986, Gallagher et al. 1988). Gradients in *S. alterniflora* densities often are attributed to nutrient limitation (Valiela et al. 1978) or soil salinity (Pennings et al. 2005, Silliman et al. 2005), but the actual mechanisms that produce the observed plant density patterns in Southeastern marshes are not understood completely. Variation in *S. alterniflora* stem density typically is counterbalanced by differences in stem height and diameter (low > mid > high) that result in greater cordgrass productivity within the low marsh (Gallagher et al. 1980, Wiegert & Freeman 1990).

The significant differences in *L. irrorata* density among marsh zones in each inlet coincided with the variation in macrophyte density. A significant shoreward increase in *L. irrorata* density from "tall" to "short" *S. alterniflora* zones occurred in this study at Hog Inlet and is reported in previous studies (Crist & Banta 1983, West & Williams 1986, Schindler et al. 1994, Lewis & Eby 2002). Previous *Littoraria* studies typically have not sampled high-marsh areas within close proximity to the terrestrial-marsh boundary. We found that *L. irrorata* density declined from the "short" *S. alterni-*

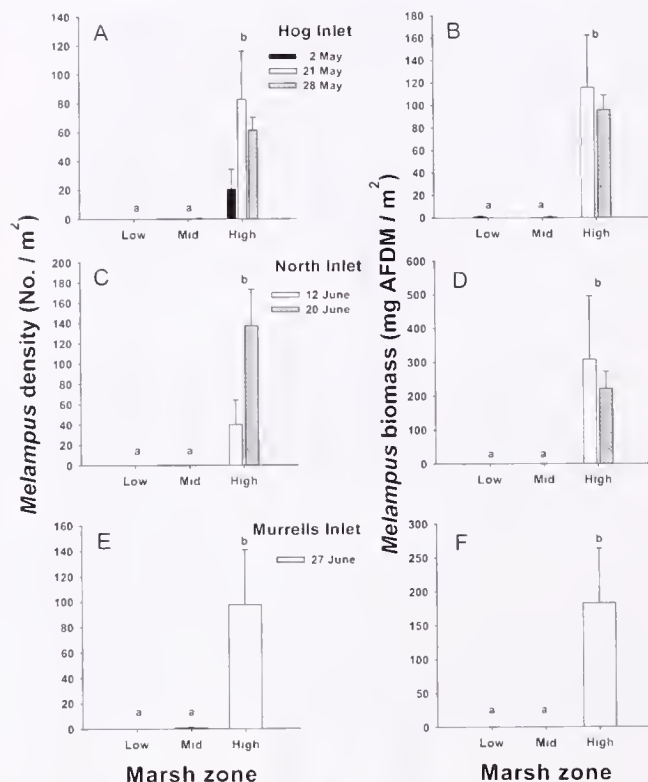

Figure 3. Mean (+1 SE) density of *Melampus bidentatus* in low-, mid and high-marsh zones of salt marshes in Hog Inlet (A), North Inlet (C) and Murrells Inlet (E). flora mid marsh to the mixed-species vegetation of the high marsh. However, *L. irrorata* density was not significantly different between high- and low-marsh zones in either Hog or North Inlet. The greater than expected snail densities suggest that the high-marsh zone may be more productive than earlier studies suggest.

Unlike the patterns in snail density, significant variation in *L. irrorata* biomass across marsh zones only occurred in one inlet (Murrells). In two inlets (North and Murrells) a shoreward increase

in biomass contrasted with the midmarsh peak in density (Fig. 2). Zonation patterns for *L. irrorata* biomass previously have not been reported, but patterns in mean shell length have been examined (Hamilton 1978, Crist & Banta 1983, Lewis & Eby 2002). Shell length increased in a shoreward direction in one study (Hamilton 1978) and decreased in another (Crist & Banta 1983). Patterns in shell length also can vary within a study, increasing shoreward in a marsh grazed by horses but decreasing in an ungrazed marsh (Lewis & Eby 2002). In both Murrells and North Inlets shell length increased shoreward corresponding to the patterns in snail biomass, but Hog Inlet snail lengths exhibited no clear trend (Fig. 4). Existing data on patterns in *L. irrorata* shell lengths are inconsistent with Vermeij's (1972) gastropod size-gradient framework: snails fit Type I and II patterns depending on the study and site. The extensive geographical range, from Virginia's Eastern Shore (Crist & Banta 1983) to Florida's Gulf Coast (Hamilton 1978), and resultant biotic (e.g., predation pressure) and abiotic differences

(e.g., tidal range) likely complicate interpretation of any shell length patterns.

Recent focus on the importance of top-down regulation of *L. irrorata* densities and ultimately salt marsh dynamics in the Southeastern US (Silliman & Zieman 2001, Silliman & Bertness 2002, Silliman et al. 2005) suggest possible mechanisms underlying any across marsh difference in snail density and size. Several studies document the effects of blue crab (*Callinectes sapidus*) predation on *L. irrorata* and the roles of tidal inundation and *S. alterniflora* density on snail predation (Hamilton 1976, Warren 1985, West & Williams 1986, Vaughn & Fisher 1988, Schindler et al. 1994, Hovel et al. 2001, Lewis & Eby 2002). Blue crab predation on snails is more pronounced closer to tidal creeks because of the increased inundation frequency and greater coverage times permitting typically subtidal predators to spend more time foraging and feeding (West & Williams 1986, Schindler et al. 1994, Lewis & Eby 2002). Along with fewer and shorter inundations in the mid

marsh, greater *S. alterniflora* stem densities hinder blue crab foraging (West & Williams 1986, Schindler et al. 1994, Lewis & Eby 2002). *Spartina alterniflora* can also provide an aerial refuge from predators once snails climb the stems (Hamilton 1976, Warren 1985, Vaughn & Fisher 1988, Hovel et al. 2001). The positive correlation between *L. irrorata* and *S. alterniflora* densities in the low-marsh zone of all inlets supports the use of stems as an important vertical refuge from predators. Similarly, West & Williams (1986) document a strong positive relationship between snails and stem density.

In contrast to *L. irrorata*, the distribution of *M. bidentatus* was restricted to the high marsh across all transects and inlets. In more northern marshes *M. bidentatus* also occurs primarily in the high-marsh, but they can also extend into the midmarsh or short-*Spartina* zone (Kerwin 1972, Price 1980, Fell et al. 1982). Our density estimates for *M. bidentatus* were often lower than those in northern Western Atlantic marshes (Table 2). The lack of any appreciable *M. bidentatus* outside of the high marsh in our study may be attributed to differences in soil salinity that result from latitudinal variation in evapotranspiration (Pennings & Bertness 1999). Similar to *L. irrorata*, *M. bidentatus* is also vulnerable to marine predators (e.g., especially *Fundulus heteroclitus*) moving onto the marsh during high tides and having a greater effect in the more frequently inundated low- and mid-marsh zones (Vince et al. 1976, Joyce & Weisberg 1986). Whether physically limited or biologically regulated to living a mostly terrestrial existence in the upper intertidal region, pulmonate *M. bidentatus* must remain in close proximity to areas of the marsh inundated by spring tides to enable development of its planktonic larvae (Russell-Hunter et al. 1972).

Snail densities for *L. irrorata* within Hog, Murrells and North Inlets were very similar to means reported in most other studies, but they were much lower than in some marshes further south, especially at Sapelo Island, GA (Table 2). A preference by *L. irrorata* for regions of higher salinity (as a result of increased

evapotranspiration) is a possible explanation, but our study inlets are ocean-dominated and some density estimates from marshes further south are similar to our own. Cross-site comparisons of population-limiting factors (e.g., predator populations, food resources, estuarine conditions experienced by veliger larvae) would be an essential step toward understanding these large differences in density among marshes.

Although variation in *L. irrorata* density has been the focus of several studies (Table 2), biomass of *L. irrorata* has seldom been estimated. In fact, none of the studies listed in Table 2, other than our own, examine variation in biomass within and among marshes. Given that most studies have found *L. irrorata* density peaking in the mid marsh, we expected biomass to show a similar pattern. Instead, the biomass of *L. irrorata* in the high marsh was unexpectedly high compared with the other two zones in North and Murrells Inlets (Fig. 2). The high-marsh prevalence of *L. irrorata* biomass is also not anticipated, given the snail's potentially obligatory association with *S. alterniflora* (e.g., Silliman & Newell 2003) and the plant's sparse occurrence in the high marsh where *S. alterniflora* is typically replaced by other halophytes (e.g., *J. roemerianus*, *S. patens*, *D. spicata*). *Littoraria irrorata* appears to be a conspicuous resident across the entire vegetated salt marsh in SC. Results from previous studies that typically focus only on the marsh near tidal creeks (Table 2) would appreciably underestimate the total population of *L. irrorata* and its overall significance within coastal marshes.

ACKNOWLEDGMENTS

Completion of this work was only possible with the help of several CCU undergraduates: Elizabeth Dukes, David Player, Azure Bevington and Lauren Greenfield. We especially thank ED and DP for measuring and weighing snails for the length-mass regressions. Financial support was provided by CCU Departments of Biology and Marine Science.

D5, 98848 Noumea, New Caledonia; ⁴The WorldFish Center, c/o Secretariat of the Pacific Community, B.P. D5, 98848 Noumea, New Caledonia

ABSTRACT Temporal variation in abundance of spat of the blacklip pearl oyster (*Pinctada margaritifera*) was determined over an eight-year period at two sites, Gizo and Noro, in the Western Province of Solomon Islands. Spat were collected by deploying shade mesh substrata at a depth of 3 m for near-sequential two-month period. Overall, spatfall at the two sites was similar, with summer maximum of 4.9 (Gizo) and 4.7 collector⁻¹ (Noro). At both sites, significantly fewer spat were collected in late winter than in summer. Abundance of spat varied among years, although there was no consistency between the two sites regarding years of highest recruitment. Maximum settlement of spat at Gizo was 10.2 collector⁻¹ in January 2002, whereas at Noro it was 19.6 collector⁻¹ in March 2000. Mean size of spat did not vary over time, but spat at Gizo were significantly smaller (geometric mean 7.6 mm) than those at Noro (mean 8.4 mm). Predators of spat settled on the collectors throughout the year; there were significantly more gastropod predators at Noro than at Gizo. Gizo and Noro in the Western Province of Solomon Islands are reliable places for collection of blacklip pearl oyster spat. Spat can be caught all year round, although collections will be most effective between November and March.

KEY WORDS: blacklip pearl oyster, spat collection, Solomon Islands, temporal variability.

INTRODUCTION

Blacklip pearl oysters (*Pinctada margaritifera*) are an economically important species in the tropical Indo-Pacific, primarily through the use of mature oysters for the culture of “black” pearls. At present, culture of black pearls in the Pacific is confined mostly to the lagoons of eastern Polynesia (Sarver & Sims 1996). In these locations, planktonic larval stages are entrained by currents within atoll lagoon systems. Expansion of the pearl industry to other parts of the region, where such lagoons are not present, requires identification of an alternative strategy for spat collection, and/or hatchery production. Friedman and Bell (1996) and Friedman et al. (1998) found that spat could be collected cheaply and easily using simple mesh bag collectors deployed on the seaward slopes of coastal coral reefs in Solomon Islands. Friedman and Bell (1999, 2000) then identified the optimal locations, site characteristics and deployment times for spat collection in Solomon Islands, and Friedman and Southgate (1999) demonstrated that the spat could be grown successfully to adult size.

A shortcoming of the studies (see earlier) on the availability of spat in Solomon Islands, and other locations in the region (Beer & Southgate 2000), is that they are short term. This poses a potential problem for investors who might consider establishing black pearl farms in the western Pacific, based on collection of wild spat. Ideally, they need a long time-series of data on abundance of spat to gauge whether sufficient oysters can be collected each year to support commercial operations.

In this study, we address this information gap for two locations in the Western Province of Solomon Islands by documenting temporal variability in abundance of blacklip pearl oyster spat on collectors deployed over an eight-year period.

METHODS

The two sites used to assess long-term variation in abundance of blacklip pearl oyster spat in this study, Noro and Gizo (Fig. 1),

were selected because they previously yielded above average rates of spat collection in Solomon Islands (Friedman et al. 1998, Friedman & Bell 2000).

The methods used to collect spat were based on those developed for Solomon Islands by Friedman et al. (1998) and Friedman and Bell (1999, 2000). At each site, 10–14 spat collectors were attached at intervals along a 100-m longline made of 12 mm polypropylene rope. Each collector comprised a 0.4 m² panel of 55% shade mesh, folded concertina-fashion, threaded and tied in a bundle with monofilament line. Anchor lines and subsurface buoys, at 20-m intervals, were used to hold the longline at a depth of 3 m. The shade mesh spat collectors were deployed every two months, for duration of two months, each year between 1997 and 2005. Deployment and retrieval of collectors at the two sites was staggered over a few days, for logistic reasons. At both sites, spat were harvested from collectors as close as possible to the last days of December, February, April, June, August and October. These dates are hereafter referred to as periods 1–6 respectively. Exceptions to this, when collections were not made, were at Noro in December 1998, and at both sites in August 2001 and December 2004.

At harvest, the size, as dorso-ventral measurement (DVM), of each live and dead spat on each collector was recorded to the nearest mm. The numbers of the two most common predators of blacklip pearl oyster spat, crabs and gastropods (*Cynatium* spp.), were also recorded each time a collector was removed from the water.

Data Analysis

The spat collector catch data were examined for variation within and between years' effects using a series of targeted analyses. For most analyses, we reduced the data from each period to average catch per collector; this accommodated the four samples where number of collectors per longline was other than 10.

Firstly, we used a 2-way ANOVA to compare differences in spat abundance, grouping by collection period and by site. ANOVA was carried out using Statistica for Windows 5.1 (Statsoft

*Corresponding author. E-mail: c.oengpepa@cgiar.org

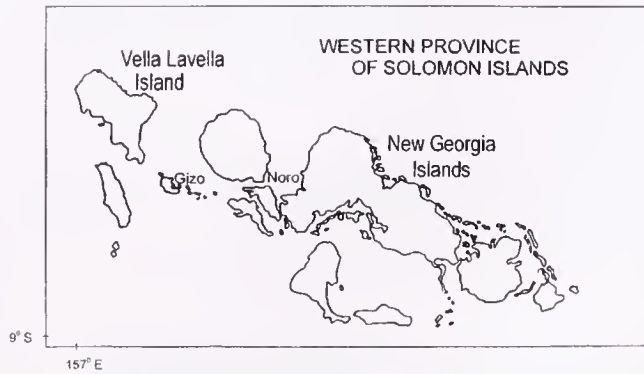

Figure 1. Location of the two sites, Gizo and Noro, in the Western Province of Solomon Islands where spat collectors were deployed in this study.

Inc., Tulsa, Oklahoma, USA). All data were transformed using $\ln(N + 1)$ but, because of the large number of zeros, the assumption of homogeneity of variance was not met. Although ANOVA is reasonably robust to deviation from this assumption (Zar 1996), we considered differences to be significant only if $P \leq 0.01$. This procedure reduces the risk of Type I errors and is particularly appropriate when sample sizes are small (Underwood 1981). Significant differences between means were identified using posthoc testing (Tukey HSD test for unequal N).

We analyzed for a monotonic, long-term trend over the entire eight-year period using simple linear regression of time versus catch (Esterby 1996). We did not consider that the dataset was long enough to examine for cyclic periodicity. Where a consistent collection period effect was identified, see earlier, data were de-seasonalized before this long-term regression analysis. In practice, this was only the case for live spat numbers, and this was accomplished by calculating deviation from the overall mean value for each sampling period.

Year-to-year variation in live spat abundance was examined by comparing catches using 1-way ANOVA. For each year where all six collection periods were available, we selected the annual maximum to overcome any effects of variation in timing of peak abundance. For this analysis, spat numbers for each of the 10 replicate collectors on each line were used after transformation, using $\ln(N + 1)$, to improve homogeneity of variances. Insufficient numbers and multiple zero values precluded such analysis of abundances of dead spat and predators.

Differences in spat sizes among collection periods were examined using a 2-way ANOVA (site \times period). Data were skewed towards small size, which was corrected by log-transformation for all tests.

RESULTS AND DISCUSSION

The long-term patterns of spat collection at the two sites showed variability in the abundance of spat and predators over time, and by site (Fig. 2). The way in which this variation was partitioned within years, between sites and between years, is outlined (see later).

Within-year and Between Site Variation

When the datasets were grouped by site and collection period, no differences were found between sites, but an effect of period was evident (Table 1). The lack of an interaction effect suggests

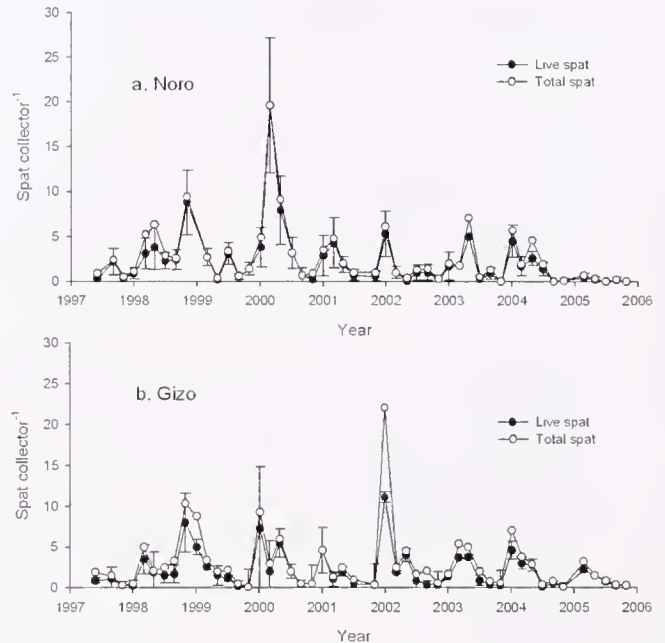

Figure 2. Mean abundance of spat (total and live) on collectors at (a) Noro and (b) Gizo in the Western Province of Solomon Islands. For each data point, $n = 9-14$ (median $n = 10$). Error bars are 95% confidence limits around live spat.

that the two sites were behaving similarly. Posthoc testing showed that the significant variation in numbers of spat collected between periods was caused by higher abundances in periods 1, 2 and 3 compared with 5 and 6, with period 4 having intermediate values. This translates to higher spatfall on collectors submerged between November and April than on those in the water from July through October. Grouped by harvest time, the lowest mean spat abundance per collector over the eight-year period for Gizo was 0.7 (June-August deployments) and the highest was 4.9 (November-December deployments). For the same approximate periods at Noro, winter yielded 1.4 spat per collector, whereas summer yielded 4.7 spat per collector. Abundances of dead spat did not differ significantly between sites but there was a significant effect of deployment period (Table 2). Once again, posthoc testing showed that collection rates were significantly lower in winter compared with summer. The pattern of a summer maximum in abundance of spat over the eight-year period was similar to that reported for the shorter study by Friedman et al. (1998). It is

TABLE 1.

	Period	5	4.43	11.3	<0.001
	Site \times Period	5	3.34	8.8	<0.001
	Residual	1794	0.39		

TABLE 2.

Results of the 2-way ANOVA of effects of deployment period and site on the number of dead *P. margaritifera*, and numbers of crabs and *Cymatium* spp. on spat collectors at Gizo and Noro. All variables were transformed using $\ln(N + 1)$. Effects considered significant are italicized.

Variable	Source of Variation	DF	MS	F	P
Dead spat	Site	1	0.72	4.81	0.03
	Period	5	0.55	3.70	0.004
	Site \times Period	5	0.29	2.94	0.10
	Residual	82	0.15		
Crabs	Site	1	0.04	0.14	0.70
	Period	5	0.64	2.05	0.08
	Site \times Period	5	0.73	2.33	0.04
	Residual	82	0.31		
<i>Cymatium</i>	Site	1	0.76	8.01	0.006
	Period	5	0.06	0.67	0.65
	Site \times Period	5	0.12	1.25	0.29
	Residual	82	0.09		

interesting that the shorter soak time of spat collectors in our study (2 months) yielded the same peak numbers of spat as the six-month soak time used by Friedman et al. (1998). This is consistent with the view that there is an optimal soak time before predators begin to overwhelm ongoing recruitment and perhaps explains why we collected relatively few (23%) dead spat compared with Friedman et al. (1996) (46%). The timing of peak spat settlement in Solomon Islands differed to that found on the Great Barrier Reef, where maximum numbers were collected during May to June (Beer & Southgate 2000). Reasons for this difference are unclear. Crabs and *Cymatium* spp. showed no consistent variation in abundance among collection periods, although *Cymatium* spp. were more abundant at Noro (average of 0.53 collector⁻¹) than at Gizo (0.33 collector⁻¹) (Fig. 3, Table 2).

Inter-annual Variation and Multiyear Trends

Live spat showed no multiyear trends in abundance after the data were de-seasonalized. Nevertheless, there were clearly differences in abundance of spat in some years, which appear to be caused by differences in timing of the recruitment peak and in size of the peaks (Fig. 2). Out of 13 site-years when a full year of data were collected, the summer peak was in period 1 in 46% of cases, period 2 in 30%, period 3 in 15% and period 6 in 8%. At Gizo, the greatest annual spatfall peak occurred in period 6 in 2001 (10.2 collector⁻¹) and at Noro in period 2 of 2000 (19.6 collector⁻¹). We examined the significance of the magnitudes of annual peaks using 1-way ANOVA for each site (Table 3). Only years when data were obtained for all sampling periods could be used, and this removed 2005 from both sites. Note that for this analysis, because of one occasion when the summer peak spat collection was in period 6 of the previous calendar year, we considered that each spat year began with period 6 of the calendar year before and ran through to period 5 of the year in question. Significantly different peak spatfalls were evident between years at both sites. Posthoc testing showed that at Noro the 2000 peak yielded more spat than any other year except 1999, whereas at Gizo, abundance in 2002 was significantly higher than in 1998, 2001, 2003 and 2004, with no other significant differences.

The number of crabs at Gizo was the only temporal dataset that

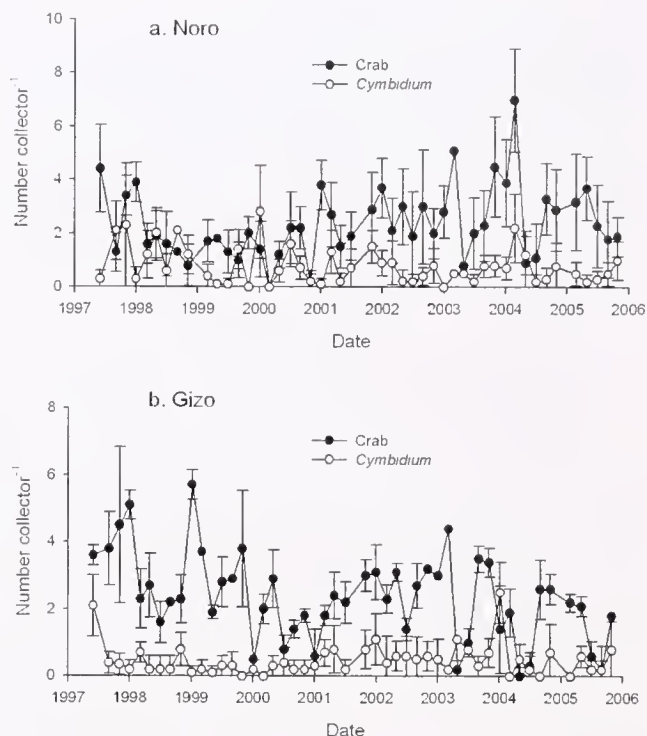

Figure 3. Mean abundance of two major predators of blacklip pearl oyster spat, crabs and *Cymatium* spp. on collectors at (a) Noro and (b) Gizo. For each data point, $n = 9\text{--}14$ (median $n = 10$). Error bars are 95% confidence limits.

showed evidence of a linear trend over time, in this case one of declining abundance (Table 4). The absence of any reciprocal effect on spat numbers shows that, under the conditions of deployment, the small changes in crab numbers did not affect spat survival.

Spat Size

There were significant differences in the mean sizes of spat harvested during each collection period and between sites (Table 1). Maximum size tended to be in period 2, towards the latter part of summer, when water temperatures can be expected to be highest. This effect was more pronounced at Gizo than at Noro. The median sizes of live spat on collectors at Noro and Gizo were 9 and 7 mm, and the geometric means were significantly different at 7.6 and 8.1 mm, respectively (Table 1). Caution should be taken in interpreting this size difference, because this result was obtained

TABLE 3.

Results of the 1-way ANOVA of effects of year on the maximum number of *P. margaritifera* spat ($\ln(N + 1)$) on spat collectors deployed at any period within that year at Noro and Gizo. Only years when data from all individual spat collectors were available for each of the six sampling periods were used in this analysis.

Site	Source of Variation	DF	MS	F	P
Noro	Year	6	2.84	6.77	<0.001
	Residual	61	0.42		
Gizo	Year	6	1.63	3.49	0.005
	Residual	62	0.46		

TABLE 4.

Site	Variable	R ²	F	dF	p	Slope ± error
Noro	Live Spat (de-seasonalized)	0.06	3.42	1,47	0.07	
	Crabs	0.06	2.53	1,47	0.12	
	<i>Cymatium spp</i>	0.06	2.44	1,47	0.12	
Gizo	Live Spat (de-seasonalized)	0.03	1.17	1,47	0.28	
	Crabs	0.16	10.3	1,47	<0.01	-0.21 ± 0.07
	<i>Cymatium spp</i>	0.00	0.11	1,47	0.74	

from a large dataset, and the differences were within the likely measurement error of spat. Thus, the ecological significance of such a small difference is questionable. The arithmetic mean of spat for both sites was 10 mm. This is consistent with the earlier data of Friedman and Bell (2000), who reported that spat attained

an arithmetic mean size of ~10–14 mm within three months of deployment of collectors.

CONCLUSION

Gizo and Noro in the Western Province of Solomon Islands are reliable places for the collection of blacklip pearl oyster spat. However, collection of spat is expected to be most cost-effective between November and March, when average yields of >4 spat per collector for two-month deployments can be expected in most years.

ACKNOWLEDGMENTS

The authors thank the staff of the WorldFish Center's Western Pacific Research Station, who worked to collect this dataset through difficult times. Mason Tauku supervised much of the fieldwork and was responsible for data entry. The authors also thank Dr Steve Purcell of WorldFish for helpful discussions on curve fitting. Funding for this work was provided partially by the Australian Centre for International Agricultural Research. Pre-submission review was kindly provided by Dr Neil Andrew. This is the WorldFish Center Contribution No. 1811.

THE LIMITS OF MORPHOMETRIC FEATURES FOR THE IDENTIFICATION OF BLACK-LIP PEARL OYSTER (*PINCTADA MARGARITIFERA*) LARVAE

ALAIN PAUGAM,¹ CHRISTINE D'OLLONE,¹ JEAN-CLAUDE COCHARD,² PIERRE GAREN^{2*}

¹Laboratoire des Sciences de l'Environnement Marin (LEMAR), Institut Universitaire Européen de la Mer, Place Nicolas Copernic, 29280 Plouzané, FRANCE; ²IFREMER, Centre du Pacifique, BP 7004, 98719 Taravao, Tahiti, French Polynesia

ABSTRACT As with most cultivated bivalves, culture of the Tahitian pearl oyster *Pinctada margaritifera* is particularly dependent on the natural environment, especially for spat supply. The ability to track in real time the abundance and the development of pearl oyster larvae in the plankton would help optimize spat collection in atolls of French Polynesia. However no identification criteria are available for the larvae of several bivalves species present in the lagoons and it is not yet possible to specifically monitor pearl oyster larvae. The aim of this study is to determine the most pertinent morphological identification criteria, to specifically identify the larvae of *P. margaritifera* and differentiate them from those of three other abundant species: *Pinctada maculata*, *Crassostrea cuculata* and *Chama* sp. The method of image analysis after photon microscopy was assessed. It allowed automatic measurement of numerous morphometric features that were tested alone or in combination and identification threshold for *P. margaritifera* larvae were determined by statistical analyses. These results led to a key that allowed correct identification for 77% of *P. margaritifera* larvae. The hinge diagnosis method under scanning electron microscopy, a prime method for the identification of specific criteria on bivalve larva shells, was also used on larvae of both *Pinctada* species. The two species could be differentiated precisely because of specific differences in the thickness of their hinge provinculum and the number of denticles it bears. However this approach is too time-consuming and technically demanding to use in real time field studies. This study showed the limitations of image analysis as an identification tool of the *P. margaritifera* larvae, but proper statistical analyses and especially the decision tree approach could be used to evaluate and efficiently prioritize the choice of the species identification criteria.

KEY WORDS: *Pinctada margaritifera*, larval identification, morphological features

INTRODUCTION

The culture of the pearl oyster *Pinctada margaritifera* (Linné, 1758) is a recent activity in French Polynesia. It developed rapidly in the 1980s and today represents the second source of income after tourism. Production reached its peak in 2000 with more than 11 tons of raw pearls with a value of 168 million Euros and generated 7,000 jobs in more than 1,000 farms spread out over some 30 islands. Subsequently, the pearl industry faced a crisis caused by a steep drop in pearl prices, which started in 2001. Export values were 122 million Euros in 2002 and 84 million Euros in 2003 for tonnages of 11 tons and 10 tons respectively. This was mostly because of a very swift and poorly controlled increase in production that entailed a perceptible drop in quality. This crisis highlighted the necessity to organize the market, and also to regulate and to sustain production.

To a large extent, the culture of the *Pinctada margaritifera* oyster in French Polynesia depends on the natural environment and it relies entirely on the supply of collected spat. The professionals set their collectors up in an empirical way based on their past observations, but spat yields show a large spatio-temporal variability (Cabral et al. 1985, Brié, pers. comm., 1999). The ability to follow-up the larvae during their pelagic life could be useful to predict the periods and places of post larvae settlement and would thus help to improve spat collection as well as spat quality. Tools are therefore needed for the identification of pearl oyster larvae in plankton samples. To our knowledge, no attempt has been made so far to identify any of the bivalve larvae present in the waters of French Polynesian atolls. Techniques allowing larvae of *P. margaritifera* to be recognized among the larvae of other bivalves

must be developed. Such approaches should, in particular, allow the distinction between larvae of *Pinctada margaritifera* and of *P. maculata* (Gould, 1850), which could be a competitor for settlement sites.

The identification of sampled larvae is always difficult and a review of techniques currently available is given in Garland and Zimmer (2002). Techniques of image analysis are explored here as a first step towards the field identification of pearl oyster larvae. The aim of this study is to evaluate the main morphological descriptors of the larvae of 4 common species in the plankton samples from Polynesian pearl farming atolls: *P. margaritifera*, *P. maculata*, *Crassostrea cuculata* and *Chama* sp. (Broderip, 1834).

Image analysis was retained as a working method to increase the number of descriptive variables of the study. Automated analysis on computer would also greatly help in reducing the subjectivity of optical methods. Univariate and multivariate statistical treatments were then applied. These methods identified the most pertinent morphological characteristics for identification of these 4 species of bivalves.

MATERIAL AND METHODS

Larval Samples From the Hatchery

The larvae of four main bivalve species present in the Polynesian atolls were reared in hatchery up to metamorphosis. *Chama* sp., *Crassostrea cuculata* and *Pinctada margaritifera* larvae were produced at the Service de la Perliculture in Rangiroa. *Pinctada maculata* and *Pinctada margaritifera* larvae were produced at Ifremer, Center du Pacifique in Tahiti.

Samples were taken on a regular basis in rearing tanks to obtain larvae of various ages ranging from 1–24 days (Table 1).

Morphological Observations

Larvae were observed with a LEITZ DMRE photon microscope. A RGB mode (Red, Green, Blue) digitized picture was acquired for each of the larvae and was analyzed with Optilab software.

Each of the RGB pictures was separated into 3 distinct layers, green, red and blue. Only the green layer was retained, because it presented the highest saturation levels and it was converted into the 256 gray level mode. The areas representing larvae were those having the highest values of gray. The automatic selection of all the pixels was done depending on their value of gray and the smallest value of gray corresponding to the bivalve larvae was empirically determined for each picture. This value was retained as

a threshold to binarize the picture. The value 1 (corresponding to the larvae) was assigned to areas with gray value greater than the threshold, and the value 0 was assigned to areas with gray value lower than the threshold. Areas of value 1 that were not complete were filled in automatically and among them, only those corresponding to individualized larvae were retained and colored in red.

The Optilab software automatically numbers the retained red colored areas and describes them by performing a series of 42 measurements such as coordinates, optical density, dimensions and

shape parameters. The best descriptors among this set of 42 were determined using principal component analysis (PCA). Six descriptors, the least dependent, were retained to establish a morphometric analysis pattern that would result in the specific identification of the 4 species of bivalves studied. They constituted the descriptive variables of larvae morphology (Fig. 1):

- the maximum intercept (Smax): length of the longest segment of the object.

TABLE 4.

Correlation matrix of the 6 least correlated parameters selected after a PCA

	Smax	2a/2b	Elong	Comp	Ftype	Ixy
Smax	1					
2a/2b	0.039	1				
Elong	0.047	0.259	1			
Comp	-0.127	-0.113	-0.524	1		
Ftype	-0.053	-0.419	-0.223	0.324	1	
Ixy	-0.035	-0.003	-0.014	-0.016	0.010	1

None of these correlations are significant at the 5% level after Bonferroni correction.

- the Ellipse Ratio (2a/2b): ratio of the major axis to the minor axis of the equivalent ellipse,
- the Elongation Factor (Elong): ratio between Smax and the mean perpendicular intercept,
- the Compactness Factor (Comp): A/A_R where A is the object area and A_R is the area of the smallest rectangle containing the object,
- the moment of inertia (Ixy) representing the pixel distribution around the Center of Mass xy: $(\sum xy) - A \cdot M_x \cdot M_y$, where xy are the pixel coordinates, M_x is the Center of Mass x $[(\sum x)/A]$ and M_y is the Center of Mass y $[(\sum y)/A]$,
- the Type Factor (Ftype): $A^2/4 \cdot \pi \sqrt{I_{xx} \cdot I_{yy}}$, where I_{xx} is the Inertia xx $[(\sum x^2) - A \cdot M_x^2]$ and I_{yy} is the Inertia yy $[(\sum y^2) - A \cdot M_y^2]$.

Data Analysis

Univariate Analysis

The morphometric measurements of 4 species were classified into 3 subgroups corresponding to the main stages of physiological

Figure 2. Correlation circle for F1 and F2 axes of the DFA applied to 6 measurements. Most of the interspecific variability (96%) is represented by Smax on F1 axis.

Individuals (F1 and F2 axes: 99 %)

Figure 3. Situation of species patches in the F1-F2 canonical space. Patches are designed to contain approximately 95% of species dots. The best species discrimination, along F1 axis, separates the genus *Pincta* on the left from *Chama* sp and *Crassostrea cucullata* on the right.

and morphological development: D larva (D), umbo larva (U) and pediveliger larva (P). An analysis of variance (ANOVA or test of Kruskal & Wallis) was undertaken for each of the 6 descriptive variables according to the species and the larval stage.

Discriminant Factor Analysis

The discriminant factor analysis (DFA) was carried out with the help of Excelstat 5.1 software. The 6 descriptors retained to specifically discriminate the larvae were not significantly correlated (the highest r was -0.524 between Elong and Comp). It was then possible to use a DFA approach to search for the combination of descriptors that maximized interspecific variability and minimized intraspecific variability (regardless of the larval stage encountered).

Decision Tree

This analysis, realized with Statistica 6 software, complemented DFA to identify larvae of the 4 species from the batches of hatchery monospecific larvae. Starting with all individuals attributed to the same species, it supplied a true-false determination model, with intermediate nodes of decision and terminal nodes of species attribution. The analysis stopped when the original species was found again with an error margin defined by the conditions for halting the segmentation, set here in advance to a minimum of 5 successive levels.

Electron Microscopy

About 10 hatchery larvae of each *P. margaritifera* and *P. maculata* species were prepared for SEM observation. Larvae were cleaned from organic matter in a bath of 10% chlorine water (Le Penneec 1978). This treatment was controlled under the microscope and was stopped by washing with distilled water as soon as degassing was observed within the valves. The prodissoconch valves were carefully separated using mounted pins and were dehydrated in a bath of 90% alcohol. They were then set up on plots for metal plating. The valves thus prepared were observed under a HITACHI-S 3200 N scanning electron microscope.

Correct identification	26%	70%	69%	60%

RESULTS

Univariate Analyses

The mean values of the 6 descriptive variables of larvae morphology (Table 2) were compared by a one-way variance analysis or a Kruskal & Wallis test (Table 3). Overall, there was no significant difference at the threshold of 5%, between means of the different groups during the larval development, except for:

- Ftype of the *C. cuculata* U stage was significantly higher than that of the D and the P stages. This was not significant however after Bonferroni correction;
- Comp of *Chama* sp was similar for the D to U larval phase but significantly smaller at the P stage; this was not significant anymore after Bonferroni correction.
- Ixy of the *Chama* species at the P stage was significantly different from that of the D or U stages even after Bonferroni correction. It also allowed to differentiate this species from the other three for the stage U, but this was not significant after Bonferroni correction;
- Smax allowed distinguishing the three main stages of larval development regardless of the species, because all comparisons within species between stage were significant even after Bonferroni correction. All comparisons between species within stage were also significant even after Bonferroni correction and Smax was especially useful to significantly differentiate the group of individuals composed of *P. margaritifera* and of *P. maculata* from the group of individuals composed by *Chama* sp and *C. cuculata*.

None of the six morphometric measurements allowed to discriminate alone the larvae of the four species. It was at best pos-

sible to distinguish individuals of *Chama* sp or of *Crassostrea cuculata* from those of *P. margaritifera* and of *P. maculata*.

Discriminant Factor Analysis

The principal component analysis (PCA) carried out on the 42 morphometric measurements allowed to retain among them the 6 least correlated parameters (Table 4).

The DFA results showed that the two first canonic axes F1 and F2 respectively represented 96% and 3% of the interspecific variability (Fig. 2). Smax corresponded mainly to F1 axis whereas Elong, in opposition to Ftype, corresponded more to F2 axis. The dot patches of the 4 species individuals are shown in the two dimensions canonical space set by axes F1 and F2 (Fig. 3). Groups of both *Pinctada* species individuals were clearly superimposed. Smax (mainly represented by F1 axis) allowed their discrimination, regardless of the larval stage, from the groups of *Chama* and *Crassostrea cuculata* species, superimposed as well. Further differentiation between the individuals of both species of *Pinctada* or between the *Chama* or *C. cuculata* species was not possible along F2 axis.

A Kullback statistical test revealed that the difference between the intragroup variance-covariance matrices was significant at 5% ($X^2 = 2340.3$; $P < 0.0001$). The barycenters corresponding to the morphometry of the 4 studied species were significantly different (Wilks Λ ratio = 0.433; $F = 99.88$; $P < 0.0001$). A DFA was carried out based on these characteristic barycenters to try species identification of each larva previously measured, but the retained discriminant morphometric features were not sufficient. The identification success rates varied depending on the species (Table 5). They were comprised between 60% and 70% for both *Pinctada* species and the *Chama* genus, whereas only 26% was achieved for the *Crassostrea* genus.

Other DFA (Tables 6, 7 and 8) were undertaken on these samples to see if better species identification could be achieved at specific larval stages with the morphometric measures at hand. The correct identification rates were quite different from one species to another, but also between larval stages. The D and P stages gave the best species identification success rates overall.

The Decision Tree

A decision tree was built to help synthesize the results of the various DFA. Each morphometric measurement was assimilated to a prediction variable (specific identification criteria). After univariate preliminary studies, they were classified according to their potential (0–100 scale) to predict the dependent variable (species identity). Ftype, Smax, Elong and the larval stage had a potential of 100, 96, 72 and 59 respectively to explain the dependent variable.

The organization of the tree was performed arbitrarily in the following manner: All of the larvae were allocated at first to the *P. maculata* species. If Smax was larger than 271 μm , the larva identity was changed for a *Chama* larva. If this condition was not true, the larva was still assigned to the *P. maculata* species until the next decision node. The overall process of the decision tree (Fig. 4) led to a discrimination key. Synthetic results of the larval identification using this discrimination key were better than those obtained with the former DFA (Table 9). However, species identification error rates were still generally higher than 25%.

Hinge Analysis by Electron Microscopy

The hinge of the umbo larva of *P. margaritifera* is made up of a narrow provinculum bearing 4 denticles on the anterior edge and 6 on the posterior edge (Fig. 5-1). The hinge of the umbo larva of *P. maculata* has a thick provinculum bearing 5 denticles on the anterior edge and 5 on the posterior edge (Fig. 5-2). There

was no individual variation within species for these traits, thus hinge analysis of larval shells allowed the formal distinction between both species of the *Pinctada* genus within the larval phase.

DISCUSSION

Thirty-four species of bivalves were found in the lagoon of the atoll of Takapoto (Salvat & Richard 1985). All of them are liable to produce larvae at the same time as the black lip pearl oyster. Therefore identification and monitoring of *P. margaritifera* larvae is not possible without means to discriminate this bivalve species from others present in the lagoon. The objective of this study was to test different morphological descriptors and to check whether the most pertinent among them could be used as tools for species determination.

The analysis of the shell profile using shape descriptors is a technique commonly used to determine numerous plankton species and was tested here. It was then related to the analysis of the hinge structure (ornamentation descriptors), a permanent criteria allowing a definite species determination (Le Pennec 1978).

Image analysis applied to morphometry has proven efficient in taxonomic identification (Garland & Zimmer 2002). This method presents the advantage of replacing the observer by algorithms and thus minimizing the risk of subjective errors. It is fast and efficient for numerous applications, such as the study of zooplankton communities. (Beaulieu et al. 1999). The data generated are useful in solving taxonomy questions and sometimes even to identify morphological variation among populations within a species (Jeffries et al. 1984, Ishii et al. 1987, Cadrin & Friedland 1999). Whereas morphometric analysis is successful at species identification in some cases, it is more difficult for a number of others. This is the case of a few copepods and fish larvae as described by Naudin et

al. (1996). The transparency of the objects to analyze is a widely encountered difficulty. In the case of bivalve larvae, the shells are translucent but their profiles are generally sufficiently contrasted from the rest of the picture and correspond to closed forms. It is then possible to use data processing tools to analyze each picture, cut out all closed forms and describe them according to contour, area and position in the picture.

The measurements performed on all of the larval stages of the 4 bivalve species studied here provided information on some of their distinctive dimensions according to age.

Univariate analyses showed that Smax was the most discriminating measure between stage within species and between species within stage. The multivariate analyses gave better results. Some degree of species identification among the larvae of the 4 species was possible, but the rates of success were different according to the methods used:

- Using DFA, the larvae discrimination of *P. margaritifera*, of *P. maculata*, of *Chama* and of *C. cucullata* was achieved with probabilities of success of 60%, 69%, 70% and of 26% respectively.
- With the decision tree approach, the larvae discrimination of *P. margaritifera*, of *P. maculata*, of *Chama* and of *C. cucullata* was achieved with probabilities of success of 74%, 63%, 69% and of 77% respectively.

Despite these positive results, the descriptors studied here cannot be considered adequate for the identification of *Pinctada* and

other bivalve larvae in plankton samples. A higher reliability and a success probability close to 90% would be required, as suggested in the literature (Jeffries et al. 1984, Naudin et al. 1996, Rahhou, 2003). Similar discrimination rates (up to 74%) between bivalve larvae were obtained by Hendriks et al. (2005), who concluded that shape characteristics combined with computer analysis did not provide tools conclusively useful for young bivalve larvae identification.

Another problem is that the acquired image of the larva form can vary between records, according to the orientation of the shell. To avoid image distortion and measurement errors, the separation plane between valves should be parallel to the sensor plane. Accuracy may also improve with additional measurement of the valve thickness. This descriptor has already been the subject of an original application as a quality indicator of larval development for *Pecten maximus* (Salaün et al. 1991). Image multiaquisition resulting from slightly moving the observed larva or changing the angle of light reaching the larva may also help in selecting larval areas that present the largest Smax.

More sophisticated mathematical contour descriptors such as Fourier descriptors (Crampton 1995) could also be considered, because it is possible to decompose the contour of an object using the Fourier elliptic transform. This method has already been proposed by Gevirtz (1976) to evaluate specific and intraspecific variability amongst bivalves, and these descriptors have been successfully used to distinguish similar mussel species (Crampton 1995, Innes & Bates 1999) and to identify eel populations based on otolith shape (Rahhou 2003). Davis et al. (1996) anticipate ongoing improvement of these visualization techniques for plankton identification, but phenotypic plasticity during larval development will limit their accuracy (Garland & Zimmer 2002).

The method of valve hinge analysis proved again its discrimination potential (Le Pennec 1978) in the present study. It enabled a definite distinction of both *Pinctada* species according to the number of denticles and to the thickness of the provinculum. However, the preparation time for each larva and the necessary handling precautions remain incompatible with the goal of a fast characterization of large-scale distributions and abundances of larvae.

Considerable progress has been achieved with other techniques

of larval identification, which are not based on the morphological but on the molecular characteristics of each species. Two tracks are being explored at this time for species identification and discrimination of bivalve larvae. One relies on genetics tools (Lopez-Piñon et al. 2002, Wood et al. 2003, Hosoi et al. 2004) and the other on immunological approach (Paugam et al. 2000, Abalde et al. 2003).

The DNA markers present the advantage of being independent of age or physiological condition of the individuals. It is therefore possible to use individual adults to develop probes that are efficient on larvae. However, their use requires in most cases that the plankton sample be destroyed, and therefore they are better suited as overall indicators of presence and representation within a sample, rather than as real probes for individual marking.

The advantage of the immunological identification over genetic identification is that the antibodies find in the plankton sample the larvae against which they have been induced and specifically mark them without altering the shell structures (Paugam et al. 2003). However the induction of an efficient antibody production requires the availability of large amounts of larvae of different species that can only be obtained in the hatchery.

The analysis of the hinge characteristics is the only method available today which would ensure identification of the *P. margaritifera* pearl oyster larvae. However, this method is too cumbersome to authorize a rapid identification of the larvae and cannot be used in real time for long term systematic plankton sampling. It could, however, be used to validate any other technique of larva, species identification. Any improvement of these techniques will be useful for following larvae within the plankton and to develop our knowledge of the larval life cycle of the *P. margaritifera* pearl oyster in the lagoons of French Polynesia.

Sucre, Venezuela

ABSTRACT Over the period from June 2002 to June 2003, we examined the relationship of seasonal changes in the mass of the gonad and somatic tissues to environmental factors for four size groups of the zebra ark shell *Arca zebra* at Chacopata, in northeastern Venezuela. The gonads of *A. zebra* began to increase in size when individuals attained 18–20 mm in shell length, but maximum gonad mass relative to somatic mass was only attained at 55–60 mm in length. Large individuals (>50 mm) showed a distinct annual reproductive cycle with a marked increase in gonad mass from July to late September 2002, coinciding with the increase in temperatures related to stratification of the water column. A decrease in gonad size occurred during October 2002 through January 2003 and coincided with a temperature decline related to renewed upwelling. The mass of somatic tissues was highest between late August to late December 2002, coinciding with the reproductive period and elevated temperatures. Other environmental factors showed little seasonal variation, although chlorophyll *a* concentration was lowest during the major period of increase in the gonad and somatic tissues (July to late September 2002), suggesting that the animals were not limited by the abundance of phytoplankton food. *A. zebra* seemed to be well adapted to the high loads of inorganic seston found in the Chacopata region.

KEY WORDS: reproduction, bivalve *Arca zebra*, Venezuela, temperature

INTRODUCTION

Both environmental factors and endogenous processes control reproductive activities in marine bivalves (Bernard 1983, Griffiths and Griffiths 1987, Thompson and MacDonald 1991). Temperature, which affects rates of many physiological processes, is the environmental factor that is most often indicated to influence reproduction in marine invertebrates (Kinne 1970). In many species, particular gametogenetic phases are associated with specific temperature conditions, and temperature changes have been indicated to stimulate maturation and spawning (Giese & Pearse 1974, Roman et al., 2001). Another important environmental factor is food availability. Energetic costs for reproduction (which are usually high) depend on food ingested, or on reserves built up during periods of high food availability (Bayne & Newell 1983, Barber & Blake 1991). Many studies have examined how reproductive activities are related to food availability, stored reserves and various environmental factors (particularly temperature and salinity) in temperate bivalve species (Mackie 1984). However, we have a much poorer understanding of such relationships in tropical species because far fewer studies have been made of tropical species (Lodeiros & Himmelman 2000).

In this study we examine changes in the mass of the gonads and somatic tissues of the tropical zebra ark shell *Arca zebra* (Swainson, 1833) throughout a year and relate the changes to environmental factors. *A. zebra*, which commonly forms dense beds on rocky bottoms between 1 and 20 m in depth, is distributed along western shores of the Atlantic Ocean from North Carolina and Bermuda to Brazil (Lodeiros et al. 1999). A large natural bed of ark shells occurs in the region of Chacopata, on the Araya Peninsula, in northeastern Venezuela. This bed covers an area of 70–80 Km² and has been intensively harvested by local fishermen for

over 25 y. About 40,000 tons are harvested per year and the income provided is second to that of the sardine in Venezuelan artisanal fisheries (Mendoza 1999, Lodeiros et al. 2005). *A. zebra* is a protandric hermaphrodite, with individuals measuring 30–65 mm (anterior-posterior axis) being predominately male, 65–80 mm individuals being male or female in equal numbers and >80 mm individuals being predominately female (Nakal 1979, García 1987). The gonads are undeveloped in 20–30 mm individuals. Gametogenesis appears to be continuous, but there are peaks in July, October and March (Mora 1985, Álvarez 1992, Saint-Aubyn et al. 1992). Relationships between the reproductive cycle and environmental changes have not been previously examined. Knowledge of such relationships is needed to develop methods for producing ark shells in a hatchery. Further, an understanding of seasonal cycles in somatic and gonad tissues is required to develop a rational strategy for the management of the ark shell fishery.

MATERIAL AND METHODS

At monthly intervals from June 2002 to July 2003, we collected samples of ark shells *A. zebra* from 3–4 m in depth from the natural bed at Chacopata (longitude between 63°46' and 63°54' and latitude between 10°42' and 10°46'). Each sample was transported (for a period of 40–60 min) in insulated boxes (at 5°C to 8°C to prevent spawning) to the Centro de Investigaciones Ecológicas de Guayacán (Universidad de Oriente) where the animals were dissected.

In the laboratory, we divided the bivalves into four groups, based on shell length (anterior-posterior axis): 10–30 mm, 30–50 mm, 50–70 mm and 70–90 mm. We analyzed 20 individuals for each size group. For each ark shell, we first removed the byssus and secondly removed epibionts and detritus from the shells. We then dissected the bivalve into three components, shell, gonad and somatic tissues. The gonad and somatic tissues were dried at 60°C

*Corresponding author. E-mail: cesarlodeirosseijo@yahoo.es

for 72 h prior to recording their dry mass. The mass of the gonad as a percentage of the mass of the somatic tissues was calculated as a gonad index.

At weekly intervals, we also took three water samples just above the beds (at 3–4 m depth) with a 5-l Niskin bottle. From each sample we first took subsamples for determinations of the oxygen concentration (Winkler method) and salinity (induction method). Then the sample was passed through a 280- μ m filter to remove macroplankton. Finally, samples were taken for determinations of the chlorophyll *a* concentration (using the spectrophotometric method, Strickland & Parsons 1972) and of the mass of organic and inorganic materials in the seston (gravimetric method). A Sealog thermograph (Vemco Ltd., Halifax, Canada) was placed on the bottom and set to record the temperature at 10-min intervals. As the thermograph only functioned from July to December 2002, we also obtained estimates of surface temperatures from satellite images that were available from the Institute of Marine Remote Sensing of the University of South Florida, USA (http://imars.usf.edu/sst/index_rm.html). We calculated mean temperatures for intervals of three days (including night and day images, but excluding cloudy period). These images were obtained with advanced very high resolution radiometer (AVHRR) sensors on a NOAA satellite.

From these images, sea surface temperature was extracted using the closest pixel to our study site. A time series of sea surface temperature was created, which was low pass filtered using of moving average with a window of three. When a cloud covered the pixel corresponding to our study site, we used the average of two pixels upstream and two downstream from our site (the mean current goes from east to west) and when this approach wasn't suitable, a gap was left. Finally, we fitted all data using the MATLAB cubic spline interpolation function (a commercial package produced by Mathsoft; www.mathsoft.com).

For the mass of the gonad and somatic tissues of each of the four size groups we first applied a 1-way ANOVA to test for variations in size over time, and then followed with a *a posteriori* Duncan tests to identify the periods when significant ($P < 0.05$) changes occurred.

RESULTS

Each of the four size groups of ark shells *A. zebra* showed changes in somatic tissue mass and gonad mass over time (one factor ANOVAs, $P < 0.05$). The seasonal changes in somatic tissue mass were greatest for the two larger size groups that measured 50–70 mm and 70–90 mm in shell length, respectively (Fig. 1). The mass increased from late June through September 2002, decreased sharply in October 2002 (ANOVA, Duncan test, $P < 0.05$), increased in over the next 2–3 mo and then decreased again during January to February 2003. After this decrease values remained low until the last month of our study (late May to late June 2003) when another increase occurred. The somatic tissue mass of 30–50 mm individuals often showed a different pattern. For example, there was a significant decrease during the first month of the study and no decrease in the last month (Duncan test, $P < 0.05$, $P > 0.05$, respectively). However, a decrease did occur during January 2003 (Duncan test, $P < 0.05$), which coincided with the decrease in the largest size groups. Finally, the smallest group, individuals measuring 10–30 mm, showed much less variation in tissue mass than the larger individuals.

The gonad mass of the two largest groups of ark shells, mea-

Figure 1. Seasonal changes in the mass of somatic tissues for 4 size groups (12–30 mm, 30–50 mm, 50–70 mm and 70–90 mm in shell length) of the zebra ark shell, *Arca zebra*, at Chacopata, in northeastern Venezuela. Vertical lines indicate standard errors.

suring 50–70 mm and 70–90 mm in shell length, respectively, increased rapidly during the first months of the study to a peak in late September 2002, and then a major decrease occurred during October 2002 through January 2003 (Fig. 2). After this decrease, the gonads remained small until the last month (June 2003) when renewed growth occurred. Surprisingly, the gonad mass was simi-

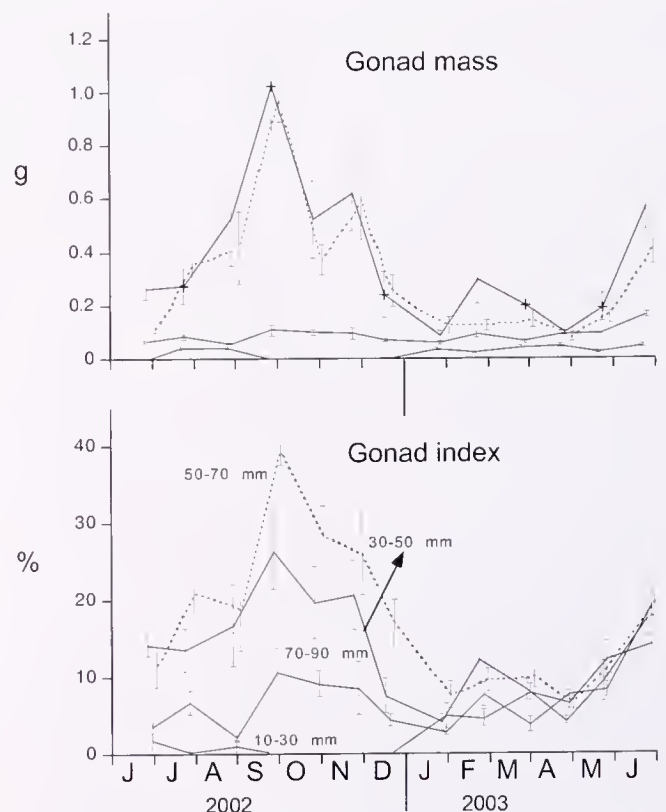

Figure 2. Seasonal changes in gonad mass and in the gonad index (gonad mass as a percentage of somatic tissue mass) for 4 size groups (12–30 mm, 30–50 mm, 50–70 mm and 70–90 mm in shell length) of the zebra ark shell, *Arca zebra*, at Chacopata, in northeastern Venezuela. Vertical lines indicate standard errors.

lar for 50–70 mm and 70–90 mm individuals (ANOVA, $P > 0.05$) on most sampling dates. As a result, relative gonad mass to somatic tissue mass (the gonad index) was usually greater for 50–70 mm individuals than for 70–90 mm individuals (Fig. 2, ANOVA, Duncan test, $P < 0.05$), especially in the period of major reproductive activity. Gonad mass of the two smallest groups of ark shells, measuring 10–30 mm and 30–50 mm, respectively, was always small (Fig. 2). Nevertheless, the relative gonad mass of 30–50-mm individuals showed seasonal variations, and the values during the last three months of our study were similar to those of larger (>50 mm) individuals. The gonad index of 10–30 mm individuals was negligible until February 2003, but then the values increased and followed a pattern similar to that in larger animals (with a marked increase during the last two months, May and June 2003).

The relation of gonad mass and the gonad index (gonad mass as a percentage of somatic tissue mass) to shell length for all individuals collected during our study provided information on the size at sexual maturity (Fig. 3). Although gonad mass was consistently low in ark shells up to a shell length of about 50 mm, the gonad index increased at 18–20 mm in shell length (up to 32%), indicating the onset of gonad production. Nevertheless, full maturity was not attained until a much larger size. For example, numerous individuals up to 37-mm in shell length had indices near 0%. Individuals measuring greater than 50–55 mm in length appeared to be fully mature, because what they had was wide spread in indices with few individuals with low indices.

Figure 3. Relation of gonad mass and of the gonad index to shell length for the zebra ark shell, *Arca zebra*, at Chacopata, in northeastern Venezuela.

Although the thermograph we placed on the ark shell bed only functioned from July to December 2002, the record was sufficient to show that the temperature record from the NOAA satellite provided a good approximation of temperatures at our study site (Fig. 4). (The satellite data were also similar to values recorded by a thermograph at Turpialito, in the Golfo de Cariaco, 10°26'56" N; 64°02'00" W; Urbano et al. 2005). Temperatures showed a progressive increase from about 24°C in July 2002 to a peak near 27°C in October and November 2002 and this corresponded to the period of stratification of the water column. Then temperatures declined to about 23°C, indicating renewed coastal upwelling, and the lowest temperature (21.3°C) was recorded in mid March 2003. After the lowest temperature was recorded, temperatures showed an upward trend until June 2003, although with considerable fluctuations indicating irregular upwelling events.

We did not observe seasonal changes in salinity. Values were generally near the yearly mean (36.7‰), although increases by up to 1‰ were recorded on a few dates (Fig. 4). Oxygen concentrations were generally high, 3 and 5 mg/L, and the only indication of a seasonal pattern was the slight decrease in oxygen levels between August and December 2002 (Fig. 4).

Figure 4. Variations in temperature, as recorded by a thermograph (grey line) and as estimated from satellite images and measurements of salinity and oxygen during the period from June 2002 to June 2003 at Chacopata, in northeastern Venezuela.

The mass of total seston varied from 20–40 mg/L over the study period and showed no distinct seasonal pattern (Fig. 5). An increased variation in values during the last four months of the study coincided with the increased temperature variations during the same period. The mass of organic seston also showed no seasonal pattern, and values only ranged from 5–8 mg/L. The proportion of inorganic seston to total seston was high, generally >70%. The concentration of chlorophyll *a* (Fig. 5) was usually in the vicinity of 1 $\mu\text{g/L}$, although sporadic increases to 2.5–5.0 $\mu\text{g/L}$ were recorded. The consistently low values recorded between late July and early November 2002, coincided with the period of high temperatures associated with the stratification of the water column.

DISCUSSION

The relation of the gonad index to shell length for the *A. zebra* showed that although the gonads begin to develop at 18–20 mm in shell length, full sexual maturity was only attained at 50–55 mm. The observations of seasonal changes in gonad indices for the four different size groups of ark shells further showed that 10–30 mm individuals had negligible reproductive output, and that 30–50 mm individuals had substantially less output than larger individuals. Individuals measuring 50–70 mm had high reproductive output, because gonad mass was similar to that of 70–90 mm individuals, and relative gonad mass was greater than that of 70–90 mm individuals.

The marked increase in gonad mass of fully mature arc shells (>50 mm) between July and late September 2002 suggested a major period of reproductive activity. This agrees with the reports of Nakal (1980) and Álvarez (1992) that the gonads of both male and female arc shells are in advanced gametogenesis stages during these months. In contrast, Saint-Aubyn et al. (1992) observed that

maximum gonad mass of *A. zebra* during 1991 was in July. Such variations likely reflect interannual differences in environmental factors, particularly factors associated with coastal upwelling, which is driven by the trade winds (Okuda et al. 1978, Lodeiros & Himmelman 2000).

The annual gonad cycle of *A. zebra* at Chacopata coincided with the seasonal changes in temperature. Both the major gonad increase from July to late September in 2002, and the beginning of a second increase during June 2003, coincided with periods of warming. Also, the decline in gonad mass from October 2002 through January 2003, likely indicating gamete release and decreased gonad production, occurred during declining temperatures. The period of minimal gonad size from February to May coincided with low temperatures. A similar positive association between reproductive activities and temperature is found in two other bivalves in northeastern Venezuela, *Perna perna* (Vélez & Lodeiros 1990) and *Lima scabra* (Lodeiros & Himmelman 1999). In contrast, in the same region, a negative relationship between reproductive activities and temperature is found in the scallop *Envula ziczac* (Lodeiros & Himmelman 2000) and the pen shell *Pinna carnea* (Narváez et al. 2000), and there seems to be no association between reproduction and temperature in the bivalves *Pinctada imbricata* (Jiménez et al., 2000), *Nodipecten nodosus* (Vélez et al., 1987) and *Pteria colymbus* (Marquez et al., 2000). Such variable relationships between reproductive activities and the annual temperature cycle in same region indicate that the different species have adopted different cues for coordinating gametogenesis events and spawning and likely contrasting strategies for providing energy for reproduction. We predict that a similar diversity of reproductive strategies exists within other invertebrate groups in the region.

The clearly annual reproductive cycle *A. zebra* was not correlated with other environmental factors, which generally showed little seasonal variation. For example, salinities and oxygen concentrations varied around the annual mean during most of the year. Also, the cycle in the mass of gonad and somatic tissues showed no relationship with food availability. In fact, the major increase in the gonad and somatic tissues in September 2002 coincided with the period of lowest chlorophyll *a* concentrations and below average levels of organic seston. These observations suggest that *A. zebra* in the Chacopata region is not limited by food availability. The inorganic content of the seston was always high in the Chacopata region (>70% of total dry seston mass) and a contributing factor could be the resuspension of materials caused by the extensive bivalve harvesting activities using drags (40,000 tons are harvested per year). Inorganic particles are often reported to be detrimental to the feeding of bivalves, because useful food particles can be strongly diluted by nonuseful particles (Riisgard 1988). However, the massive size of the arc shell population in the region, suggests that *A. zebra* is well adapted to the high levels of inorganic particles. This may be because of its ability to markedly increase its organic intake (by 31%) by selecting food particles, as reported by Ward and MacDonald (1996).

We show that the annual pattern of reproductive activity in *A. zebra* is positively associated with the temperature cycle, with the increased activity during August to December, which coincides with increased temperatures caused by stratification of the water column. This indicates that control of temperature will be an important in developing methods for producing spat in a hatchery. As the present rules controlling the arc shell fishery only limit har-

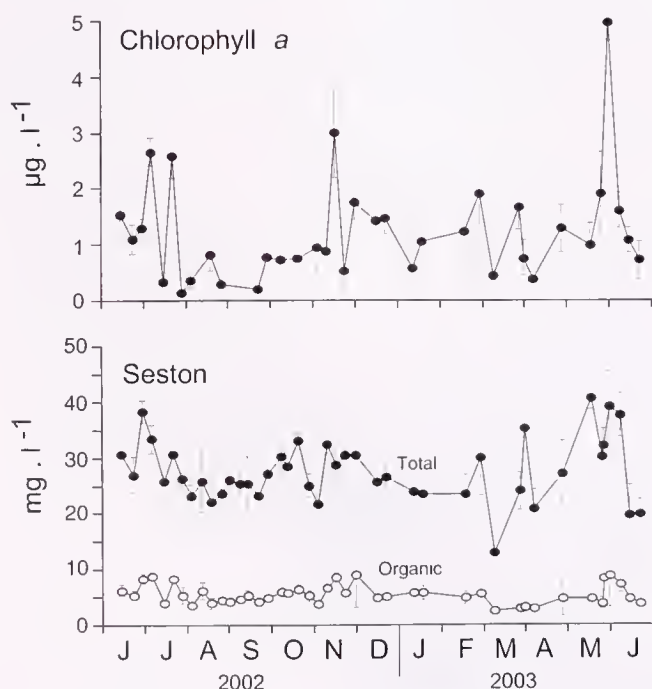

Figure 5. Variations in phytoplankton abundance as indicated by chlorophyll *a* concentration, and in the mass of total seston and organic seston during the period from June 2002 to June 2003 at Chacopata, in northeastern Venezuela.

vesting during May to August (Novoa et al. 1998), the stocks are being harvested during the reproductive period. This strategy clearly provides greater tissue mass to the fishery, but it may also limit the production of new individuals. Surprising, an extremely high biomass of arc shells has been taken from the Chacopata bed for more than 25 y. Studies are required to provide insights into the mechanisms permitting this unusually high productivity and sustainability.

ABSTRACT To determine whether DNA could be isolated from tissues obtained by brush-swabbing the mantle, viscera and foot, mantle-clips and swabbed cells were obtained from eight *Quadrula pustulosa* (Lea, 1831). DNA yields from clips and swabbings were 447.0 and 975.3 ng/μL, respectively. Furthermore, comparisons of sequences from the ND-1 mitochondrial gene region showed a 100% sequence agreement of DNA from cells obtained by clips and swabs. To determine the number of swabs needed to obtain adequate yields of DNA for analyses, the viscera and feet of 5 *Q. pustulosa* each were successively swabbed 2, 4 and 6 times. DNA yields from the 2, 4 and 6 swabbed mussel groups were 399.4, 833.8 and 852.6 ng/μL, respectively. ND-1 sequences from the lowest yield still provided 846–901 bp for the ND-1 region. Nevertheless, to ensure adequate DNA yield from cell samples obtained by swabbing, we recommend that 4 swab-strokes of the viscera and foot be obtained. The use of integumental swabbing for collection of cells for determination of genetic relationships among freshwater mussels is noninvasive, when compared with tissue collection by mantle-clipping. Therefore, its use is recommended for freshwater mussels, especially state-protected or federally listed mussel species.

KEY WORDS: Unionidae, genetics, integument, swabbing, mantle-clipping

INTRODUCTION

The use of mantle-clipping for biopsy has become a common technique for collection of tissues from unionoid mussels for genetic analyses (Buhay et al. 2002, Eackles & King 2002, Jones et al. 2004, Curole et al. 2004, Campbell et al. 2005, Geist & Kuehn 2005, Grobler et al. 2006). Berg et al. (1995) observe no significant differences in mortality rates in mantle-biopsied versus nonbiopsied mussels, *Actinonaias ligamentina* (Lamarck, 1819) and mapleleafs, *Quadrula quadrula* (Rafinesque, 1820). However, mantle-clipped snuffboxes, *Epioblasma triquetra* (Rafinesque, 1820), showed a mortality rate of 56.3% ($n = 16$) after 1.5 y of postbiopsy observation at the Aquatic Wildlife Conservation Center (AWCC) (Eckert, N., VDGF, Marion, Virginia, pers. comm.). Although mortality of mantle-clipped mussels may not be attributed directly to tissue removal, inspection of the dead *E. triquetra* showed regression of the nacre and shell deformity in the valve locations where mantle edges were removed (Fig. 1). Because mantle biopsy is an invasive procedure that may induce mortality, its use on federally endangered mussel species is a questionable procedure for genetic analyses. The goal of this study was to determine whether a procedure less invasive than mantle biopsy is available for collection of DNA for genetic analyses. Our objective was to determine whether viable DNA could be obtained by integumental swabbing from pimplebacks, *Quadrula pustulosa* (Lea, 1831) and to confirm mtDNA sequence agreement among tissues obtained from swabbing and mantle-clipping from the same mussels.

MATERIALS AND METHODS

Tissue Collection

Tissues were obtained from *Q. pustulosa* at the Freshwater Mollusk Conservation Center, Virginia Tech, Blacksburg, Virginia

($\bar{x} = 70.7$ mm, $s = \pm 11.7$). To test the feasibility of isolating DNA by swabbing of the viscera, foot and mantle, we initially sampled both mantle clips and brush swabs from 8 *Q. pustulosa*. Clips (approximately 3 × 5 mm) were taken from the edge of the mantle and stored in 95% ethanol. Cell samples were taken by using approximately 8 vigorous strokes with a bristle brush (CYB-1; Gentra Systems, Minneapolis, Minnesota). Strokes covered all structures within the visceral cavity, including the mantle surface, viscera and foot. Brush tips were stored in lyses buffer. Then, we determined (1) the amount of DNA that can be obtained using a bristle brush, compared with conventional mantle clips; (2) whether ND-1 could be amplified from the DNA and (3) whether ND-1 sequences amplified using buccal swabs was identical to results from mantle clips.

Because excessive scrubbing with bristle brushes resulted in some disruption of the mantle, we also investigated a collection technique using the viscera and foot only. Furthermore, it would be informative to determine the minimum number of integumental swabs required to provide an adequate amount of mtDNA for sequence analyses. For this objective, we sampled an additional 15 individuals of *Q. pustulosa*, using 6 passes of the brush on each of 5 individuals, 4 passes on another 5, and 2 passes on the 5 remaining mussels. Care was taken to rotate the brush between strokes and thus present a clean surface for collection at each stroke. After determining the amount of DNA obtained using each number of strokes, the ND-s gene region was sequenced from the least invasive technique (2 strokes) to test the feasibility of using this as a source of DNA for sequencing reactions.

DNA Extraction

DNA was extracted from all samples using the Purgene DNA extraction kit. For extraction from brushes, the protocol described by Purgene was modified by increasing the initial amount of lyses buffer used from 300 μL to 450 μL, to ensure complete coverage of brush-bristles in a 1.5 mL Eppendorf tube. DNA was extracted

Figure 1. Shell of *Epioblasma triquetra* showing regression of nacre in the location of mantle edge removal (arrow), following postmantle clipping observation for 1.5 y.

from mantle-clipped tissue following the standard Puregene protocol for solid tissue.

Molecular Analysis

We used the NADH dehydrogenase (ND-1) mitochondrial gene region to verify that DNA obtained from swabs was indeed mussel DNA and that it was suitable for sequencing reactions. Primer sequences and polymerase chain reaction (PCR) amplification conditions were as reported by Buhay et al. (2002) and Serb et al. (2003). Primer sequences were forward: 5'-TGGCAGAAAAGTGCATCAGATTAAAGC-3'; reverse 5'-CCTGCTTGGAAGGCAAGTGACT-3'. PCR reaction mixtures contained 100 ng of genomic DNA, 1× PCR buffer, 4.0 mM MgCl₂, 0.4 mM dNTPs, 1.0 μM of each primer and 1.5 U AmpliTaq Gold DNA polymerase, with ddH₂O added to a total volume of 25 μL. The thermal cycler profile consisted of an initial 95°C for 8 min; followed by 35 cycles of: 94°C for 40 sec, 50°C for 60 sec and 72°C for 90 sec; with a final extension step at 72°C for 2 min; and a final hold at 4°C.

PCR products were purified using a Qiagen DNA Purification kit and were sequenced using Applied Biosystems Big Dye v.3.1. Reaction mixtures consisted of 30 ng PCR product, 5-μM primer, 2 uL Big Dye 3.1 (diluted 1:1), with ddH₂O added for a final volume of 7.5 uL. The cycle reaction consisted of 30 cycles, each of 94°C for 30 sec, 50°C for 15 sec and 60°C for 4 min. The products were cleaned by centrifuging through hydrated Sephadex (Sigma) in Millipore filter plates, dried down and resuspended in Hi-Di Formamide (Applied Biosystems). The samples were denatured at 95°C for 5 min, and cooled to 4°C for 2 min before being loaded on the Applied Biosystems DNA Analyzer 3730 for processing. SEQUENCHER software (ver. 4.11) was used to align and edit sequences from stored GENESCAN files.

RESULTS

The average DNA yields obtained varied by collection technique (Table 1). The standardized collection method from mantle clips yielded an average of 447.0 ng/μL. Eight vigorous passes of the bristle brush over the viscera and mantle yielded an average of 975.3 ng/μL (with high deviations in yield), whereas swabs of the

viscera and foot yielded 852.6, 833.8 and 399.4 ng/μL using 6, 4 and 2 strokes, respectively (and with lower standard deviations compared with strokes involving the mantle). During DNA isolation, the amount of protein in mucous-derived samples was very high, and care had to be taken to ensure full precipitation of proteins before continuing with the isolation procedure. It was necessary to repeat the protein precipitation stage of the Puregene procedure in some instances.

Sequences for the ND-1 gene region obtained from mantle clips and integument swab samples from the same three individuals aligned with 100% accuracy (847–895 basepairs; Genbank accession numbers DQ640237 to DQ640239). Sequences of ND-1 for DNA isolated after 2 strokes of the bristle brush yielded a clean 846–901 bp for the ND-1 region in two random samples (Genbank accession numbers DQ640240 and DQ640241).

DISCUSSION

Comparison of our data shows that swabbing of the foot and viscera of *Q. pustulosa* is a reliable method for collection of cells for DNA analyses. The DNA obtained from the swabbing technique was pure mussel DNA; our analyses show that it is of high quality, with 100% sequence alignment with DNA obtained from mantle clips from the same mussel specimens. The DNA yield from cells collected by swabbing was equal or greater than the yield from mantle clips. Our data show that 2, 4 and 6 swab passes over the foot and viscera provided sufficient quantities of DNA for reliable analyses. Because the DNA yield remains relatively constant with 4 and 6 swabbings (852.6 and 833.8 ng/μL), and then declines with 2 (399.4 ng/μL), we recommend that 4 swabs of the foot and integument be used as a standard method for collection of cells. The number of swabs required to provide sufficient cell samples for analyses may vary by mussel size and species. We recommend that researchers use this swabbing protocol rather than tissue collection by mantle-clipping, because it is noninvasive and provides reliable DNA for genetic analyses. This is especially true for federally listed mussels, typically restricted from intentional sacrifice in federal collection permits.

We observed a high protein yield in the swabbed samples that could possibly interfere with the results of future DNA analyses. We hypothesize that this protein was included in integumental mucous that was sampled inadvertently with swabbed cells. We recommend special care be exhibited during the protein-precipitation step of DNA isolations from swabbed samples.

TABLE 1.

Results of DNA extraction from mantle and integument samples.
n = number of mussels tested.

Cell Collection Technique	Tissue Source	Number of Swab Strokes	n	Mean DNA Yield (ng/μl)
Mantle clipping	Mantle		8	447.0 ± 143.3
Integument swabbing	Viscera and mantle	8	8	975.6 ± 779.5
	Viscera and foot	6	5	852.6 ± 237.4
	Viscera and foot	4	5	833.8 ± 317.0
	Viscera and foot	2	5	399.4 ± 83.5

EFFECT OF TEMPERATURE, SEXUAL MATURITY AND SEX ON GROWTH, FOOD INTAKE AND GROSS GROWTH EFFICIENCY IN THE “PULPITO” *OCTOPUS TEHUELCHUS* (D’ORBIGNY, 1834)

M. JAVIER KLAICH^{1,2*}, MARÍA E. RÉ² AND SUSANA N. PEDRAZA^{1,2}

¹Universidad Nacional de la Patagonia San Juan Bosco, Boulevard Brown 3700, Sede Puerto Madryn, Chubut, Argentina; ²Centro Nacional Patagónico, CONICET, Boulevard Brown s/n, 9120 Puerto Madryn, Chubut Argentina

ABSTRACT The effects of temperature (10 °C and 15 °C), sexual maturity (immature and mature) and sex on instantaneous growth rates, daily feeding rates and gross growth efficiency were studied in the “Pulpito,” *Octopus tehuelchus* (d’Orbigny, 1834), under laboratory conditions. At 15 °C, immature octopus showed higher instantaneous growth and daily feeding rates than individuals maintained at 10 °C ($P < 0.01$). At 10 °C, immature individuals showed higher daily feeding rates than mature specimens ($P < 0.01$). Aside from a lack of measurable growth observed in mature males, sex appears to have had no effect on either instantaneous growth or daily feeding rates in either maturity stage or temperature treatment ($P > 0.05$). An alternative method to compare gross growth efficiencies (GGE) among 6 treatments, based on the relationship between growth and food intake, is proposed. Immature octopuses at 10 °C showed a higher GGE value than at 15 °C ($P < 0.05$). Mature individuals at 10 °C were less efficient in using food in growth than immature ones. GGE value (52%) found for immature octopus at 10 °C is among the highest reported in the literature. This could have important implications for a possible rearing activity of this species. Mature males and females at 10 °C showed a lower GGE (35.5%) than immature individuals held at 10 °C (GGE = 52%) and 15 °C (GGE = 44%). Food intake, growth and food conversion are linked processes, which in *O. tehuelchus* are influenced by temperature and sexual maturity. In addition, whereas classic statistical tests failed to detect any of these effects on GGE, the alternative method here proposed based on the relationship of growth versus food intake was successful.

KEY WORDS: *Octopus tehuelchus*, gross growth efficiency, food intake, temperature, sexual maturity, Southwestern Atlantic

INTRODUCTION

The “Pulpito,” *Octopus tehuelchus* (d’Orbigny, 1834) has an important role in octopus artisanal fishery in Argentina. The main capture period takes place from December to March–April with an official annual mean capture of 20 tons (Ré 1998 a). *O. tehuelchus* is distributed from Porto Seguro (17°S), Brazil to San Jorge Gulf (45°S), Argentina and has an intertidal distribution from San Blas Bay (40°S) to Rawson (43°S), Argentina (Ré, 1998b). This species has a marked seasonal growth, increasing its food intake activity and growth rates as temperature increases and down these rates when temperature decreases with means of $10 \pm 1^\circ\text{C}$ for the colder months and $15 \pm 1^\circ\text{C}$ for the warmer months. *O. tehuelchus* has a life-span of 18 mo of duration with dorsal mantle length and body weight of first maturation for males and females of 38mm–18g and 52mm–40g respectively (Ré, 1989). Despite its economical importance to rural communities, there is no information about the effects of temperature, sexual maturity and sex on growth, food intake and gross growth efficiency under laboratory conditions in terms of a possible complementary rearing activity. Such basic studies are necessary to understand the relationship between environment conditions on food intake, growth and life-span of a species in both natural and laboratory conditions.

In cephalopods, growth and food intake are strongly dependent on a suite of biotic and abiotic variables. Water temperature and ration levels are implicated as factors most obviously responsible for variations in growth (Mangold 1983, Forsythe & Toll 1991). Final size of male and female cephalopods may vary greatly among individuals of the same species, depending on factors such as food availability and quality, and temperature (Van Heukelem 1979). Such differences in the final size typically become dramatic only in mid to later life with the approach of sexual maturity

(Forsythe & Van Heukelem 1987). In addition, there also appears to be much individual variation in growth rate and final size even within groups or siblings reared under identical conditions (Semenov et al. 2004).

The cephalopod literature contains few studies reporting relationships between growth and food intake. In octopus, the functional relationship between growth and food intake appear to be linear above maintenance requirement (Van Heukelem 1976, Joll 1977), and it depends mainly on the organism’s efficiency at converting food into tissue growth and on physiological constraints. This relationship has been studied in laboratory conditions for only three tropical-subtropical species, *Octopus maya* (Voss/Solís Ramírez 1966), *O. cyanea* (Gray, 1849) (Van Heukelem 1976) and *O. tetricus* (Gould, 1852) (Joll 1977); no information is available for temperate species.

For many purposes, one of the most useful energetic measures is the gross growth efficiency (GGE), which expresses the amount of food intake required to fuel a unit amount of growth. It should be recognized, however, that any value calculated for GGE will vary with circumstances (temperature, locomotor activity, and similar) and is also dependent on food intake itself (specific dynamic action, maintenance ration) (Wells & Clarke 1996). The simplest way to resolve this discrepancy is to compare the growth of animals at different ration levels and estimate the maintenance ration in terms of the weight of food is required to maintain a stable weight (O’Dor & Wells 1987). With this information we would be able to calculate the partial growth efficiency (PGE), which is the efficiency of the organism at converting food into growth, after the maintenance requirements have been satisfied (Kleiber 1961). In young stages of cephalopods very high relative growth rates may be achieved and although feeding rates increase with temperature, there is no empirical evidence that GGE change detectably with temperature (Mangold & Boletzky 1973, Van Heukelem 1987). Aguado Giménez and García García (2002) by mean

*Corresponding author. E-mail: mjklaich@yahoo.com

of a multiple regression analysis observed in *O. vulgaris* (Cuvier 1797) a temperature dependence of GGE. Considering that GGE is a ratio of two variables (growth/food intake): are the classics statistics tests adequate to detect such differences between two or more GGE samples measured on two or more conditions? Moreover, could the great individual variability reported in cephalopods reduce the probability to detect differences between GGE under different conditions?

The aims of this work are to study the effect of temperature, sexual maturity and sex on the growth, food intake and gross growth efficiency of the octopus, *Octopus tewelchus*, under laboratory conditions. Specifically, we wanted to investigate the effectiveness of the relationship between growth and food intake as an alternative method to identify the response of gross growth efficiency to temperature, sexual maturity and sex. Finally, to compare the results of this alternative method with those obtained using the classics statistics test.

MATERIALS AND METHODS

Experimental Conditions

Octopuses were collected from tidepools in the intertidal zone of Puerto Lobos (42°S, 46°06'W, San Matías gulf, Argentina). Immature specimens were collected in November (late spring) 2001 and mature specimens were collected in March (early autumn) 2001. In the laboratory, octopuses were acclimatized in glass aquaria for 14 days. Octopuses were classified as immature when their body weights were lower than 18 g for males and lower than 34 g for females. For each group of immature and mature individuals, 4 experimental conditions were established: (1) males and (2) females at a 10°C water temperature, (3) males and (4) females at a 15°C temperature. Every 10 days, food intake and growth were measured over a period of 50 days for mature octopuses and 30 days for immature ones. Note the high mortality and escapement resulted in two entire missing treatments (i.e., mature males and females held at 15°C). Therefore, 6 treatments were used instead of the 8 originally proposed. For each of the 6 treatments, 5 isolated octopuses per aquaria were used. Before the end of the immature period an unbalanced design was the result of 2 immature males dead kept at 15°C. Because of this set back, only 11 records of food intake and growth were available to compare with the other 5 treatments. In consequence, to perform the statistic tests that require a balanced design, 11 measurements pairs food intake-growth were randomly chosen from each of the others 5 treatments.

Over the whole trial the light regimen was of 8 h light and 16 h darkness, and octopuses were fed daily on a monospecific diet with live crab (*Cyrtograpsus altimanus*), which has a good acceptability in laboratory conditions (Ré & Gómez Simes 1992). Each octopus was fed with one crab, which was chosen randomly with a minimum of 3% and a maximum of 17% of octopus's body weight. The effective percentage offered to each octopus was defined as a daily ration for that day. Any predated crabs were replaced with crabs of known wet weight. The weights of live crabs remaining and the unconsumed remains of predated crabs were recorded to establish the weight of tissue ingested.

Food Intake

The amount of food intake by each octopus at intervals of 10 days was calculated for immature and mature individuals over

periods of 30 and 50 days respectively. The individual daily feeding rates were calculated following Choe (1966):

$$DFR = FI/(t * W) * 100$$

where *FI* is the total food intake (in grams) over time period (*t* = 10 days); *W* is the average of the weight measured at the beginning and end of each 10-day period. ANOVA was used to compare DFR between treatments. Because the two missing treatments (i.e., mature males and females held at 15°C) two analysis of variance tests were performed to evaluate the effects of temperature and sex on DFR in immature individuals and the effects of sexual maturity and sex on DFR in individuals kept at 10°C. In all cases the number of observations was 11 per treatment.

Growth Measurements

To monitor individual change in wet weight, all specimens were weighed at intervals of 10 days throughout the trial. Specimens were removed from their aquaria and weighed in a plastic beaker on a digital balance (Mettler, model PC 440) to the nearest centigram. The octopuses were not anaesthetized, and the period of handling during weighing was kept brief to minimize stress to the animal. Least-squares linear regression was used to calculate instantaneous growth rates (*G*), expressed as the percent increase in body mass per day (Forsythe & Van Heukelem 1987). *G* values were compared among treatments by a parallelism test (Zar 1996).

Growth Versus Food Intake

Growth and food intake (as a percentage of body weight) were calculated at 10 days intervals to study the relationship between growth and food intake under the experimental conditions. For each octopus, these values were calculated as follows:

$$FI(\%) = (FI/BW_i) * 100,$$

where *BW_i* is the octopus wet weight (in grams) at the beginning of each time interval, and:

$$\Delta BW(\%) = (\Delta WB/BW_i) * 100,$$

where ΔBW is the difference between the weight at the beginning and end of each time period (*t* = 10 days).

Following Van Heukelem (1976) and Joll (1977), the relationship between $\Delta BW(\%)$ versus *FI*(%) was investigated using the linear model:

$$\Delta BW(\%) = b * FI(\%) + a \quad (1)$$

where *b* is the slope and *a* is the intercept, which estimates the weight lost at starvation condition (i.e., when food intake is equal to zero). Note that *a_i* will always be negative because this is an estimate of the weight lost at starvation condition. The slopes and intercepts were compared among treatments using parallelism and ANCOVA tests (Zar 1996) respectively.

For each treatment, the maintenance level (ML) was calculated from Eq. 1 (as a percentage of body weight) as:

$$ML(\%) = -a/b \quad (2)$$

This follows the recommendation of Wells and Clarke (1996). From *ML*(%) definition, Eq. (1) can be rewritten using *ML*(%) as a new parameter in the function:

$$\Delta BW(\%) = b * [FI(\%) - ML(\%)]$$

Following the definition of Kleiber (1961), *b* is the partial growth

efficiency (PGE) of conversion of the food remaining after the maintenance requirements have been satisfied, then:

$$\text{PGE} = \Delta\text{BW}(\%) / [\text{FI}(\%) - \text{ML}(\%)]$$

Gross Growth Efficiency

The gross growth efficiency (GGE) was calculated following Choe (1966):

$$\text{GGE} = [\Delta\text{BW}/\text{FI}] \times 100 \quad (4)$$

where ΔBW is the change in wet weight (in grams) and FI is the food intake (in grams) over each period of 10 days. The variance of GGE estimates were obtained using the delta method (Seber 1982), to include the variability caused by ΔBW and FI estimation.

Using the relationship between $\Delta\text{BW}(\%)$ and $\text{FI}(\%)$, an alternative criterion can be defined that could allow comparing gross growth efficiencies calculated under two or more treatments. Let T_1 and T_2 be two treatments under the relationship between food intake and growth is estimated, then from Eq.(1):

$$\begin{aligned} \Delta\text{BW}(\%)_1 &= b_1 \times \text{FI}(\%)_1 - a_1 \quad \text{and} \quad \Delta\text{BW}(\%)_2 \\ &= b_2 \times \text{FI}(\%)_2 - a_2 \end{aligned}$$

If $b_1 = b_2$ then, for an equal food intake value of $\text{FI}(\%)$ the change in wet weight $\Delta\text{BW}(\%)$ values under treatments T_1 and T_2 will depend on intercepts a_1 and a_2 because:

If

$$-a_1 > -a_2 \quad \text{then,} \quad \Delta\text{BW}(\%)_1 > \Delta\text{BW}(\%)_2,$$

therefore:

$$\begin{aligned} \text{GGE}_1 &= [\Delta\text{BW}(\%)_1 / \text{FI}(\%)] \times 100 > \text{GGE}_2 \\ &= [\Delta\text{BW}(\%)_2 / \text{FI}(\%)] \times 100 \end{aligned}$$

Thus, a difference between a_1 and a_2 will indicate a difference between gross growth efficiencies calculated under treatments T_1 and T_2 . The gross growth efficiencies were compared among treatments by means of the criterion established earlier. The results obtained with this alternative method, were compared with those obtained using the classical statistical approach: (a) a direct comparison between intervals of confidence at 95% of GGE for immature octopuses kept at 10°C and 15°C, and (b) a t'Welch approximation test for disparate variances to compare GGE of immature and mature octopuses kept at 10°C.

Because a marked difference exists between the process of gain and loss weight, only positive values were used to investigate the effects of temperature, sex and sexual maturity on GGE. In fact, the effect of temperature, sex and sexual maturity on weight loss will be studied using the ANCOVA analysis.

RESULTS

Food Intake

Means of daily feeding rates (DFR) obtained for males and females, temperature levels and sexual maturity stages are shown in Table 1. Immature octopus of both sexes showed significantly higher DFR when held at a higher temperature value (15°C) than those held at a lower temperature value (10°C) ($P = 0.0001$), whereas no effect of sex was found ($P = 0.1301$) on DFR. Mature individuals at 10°C had a significantly lower daily feeding rate than immature octopuses held at the same temperature ($P = 0.0312$). There was no sex-based difference between DFR of ma-

TABLE 1.

Daily feeding rate mean values obtained for mature *Octopus tehuelchus* held at 10°C and immature specimens held at 10°C and 15°C.

Temperature (°C)	Immature			Mature		
	Males	Females	Both sexes	Males	Females	Both sexes
10	1.42	1.46	1.44	0.93	1.25	1.09
15	1.96	2.47	2.21	—	—	—
10 and 15	1.69	1.96	1.82*			

For all treatments $N = 11$.

(*) = Overall mean; (—) = No value is presented because of both scaping and high mortality in these treatments.

ture and immature animals of the same maturation stages when kept at 10°C ($P = 0.2457$).

Growth

By means of adjusted R square criterion, for both immature individuals and mature females, the best fit to the observed growth over time was an exponential curve, whereas mature males showed a linear growth as a best fit (Fig. 1). The slopes of the regressions for all treatments were positive. When each slope, as the instantaneous growth rate (G), was tested for significance of difference from zero, the slopes for immature individuals under 10°C and 15°C, and mature females held at 10°C, were all significantly different from zero ($P < 0.05$), whereas the slope for mature males was not ($P = 0.7780$). Immature octopuses held at 15°C grew faster than those at 10°C ($P = 0.0061$). No differences were found between G values of immature individuals at 10°C and mature females kept at the same temperature ($P = 0.1561$). The values of instantaneous growth rates for immature individuals at 10°C and 15°C and mature octopuses at 10°C are showed in Table 2.

Growth Versus Food Intake

For all treatments the best fit for the relationship between growth and food intake was linear (Fig. 2 and Fig. 3) and Table 3. The slope b , as the partial growth efficiency (PGE) for each experimental condition was positive and significantly different from zero (Table 3). Parallelism tests indicated no difference between PGE of immature octopuses at 10°C and 15°C ($P = 0.5972$). For mature individuals, the parallelism test showed no difference between PGE of males and females kept at 10°C ($P = 0.7618$).

These results indicate that when maintenance requirements were satisfied, an equal portion from food remaining was invested in growth by immature octopus at 10°C and 15°C. The same situation was observed between mature males and females kept at 10°C. For immature individuals, weight lost (WL) as the percentage of body weight for an interval of 10 days was significantly higher in octopus kept at 15°C than those at 10°C ($P = 0.0352$). No difference was found between WL for males and females at mature stage kept at 10°C ($P = 0.3075$). The maintenance level (ML) in immature octopuses at 15°C was greater than those at 10°C and no effect of sex was observed on ML. There was no difference between ML of males and females at mature stage kept at 10°C. Results of simple regression analyses are showed in Table 3.

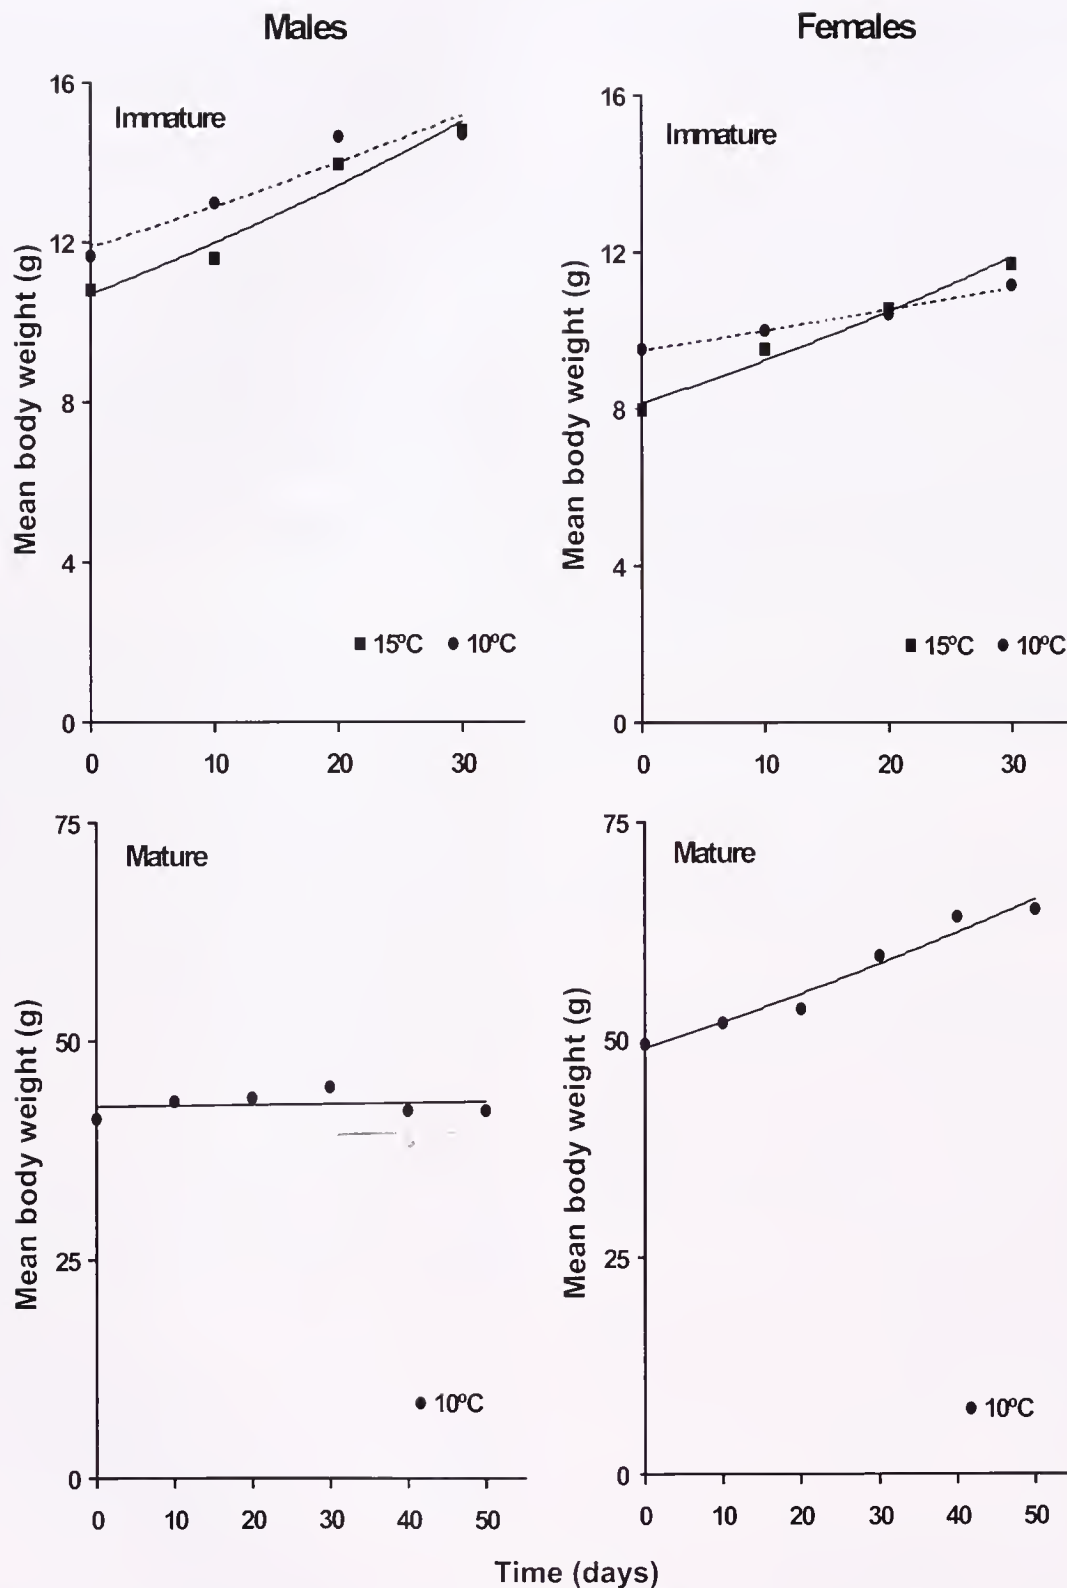

Figure 1. Mean body weight ($n = 5$) of *O. tehuatlus* in grams for each treatment versus time in days. Both dash and solid lines represent the estimated curve for each treatment.

Gross Growth Efficiency

Gross growth efficiency (GGE) mean values indicated that immature octopuses of both sexes at 15°C invested 44% from total

ingested food in growth, whereas 52% of ingested food was invested in growth at 10°C. When negative growth data were excluded from the analysis, GGE mean value for mature individuals of both sexes kept at 10°C was 35.5% of total food intake. A

TABLE 2.

Instantaneous growth rates (G) estimated for mature *O. tehueltchus* held at 10°C and immature specimens held at 10°C and 15°C.

Temperature (°C)	Immature			Mature		
	Males	Females	Both sexes	Males	Females	Both sexes
10	0.78	0.53	0.67	0.05	0.60	0.32
15	1.05	1.28	1.19	—	—	—
10 and 15	0.97	0.89	0.93*	—	—	—

(*) = Overall mean; (—) = No value is presented because of both scaping and high mortality in these treatments.

significant individual variation in GGE was observed for all analyzed treatments (Table 4). No difference between the variance of GGE for immature individuals at 10°C and 15°C was found ($P > 0.05$). However, GGE variance of mature octopuses kept at 10°C was significantly different from that of immature individuals calculated under the same temperature treatment ($P < 0.001$).

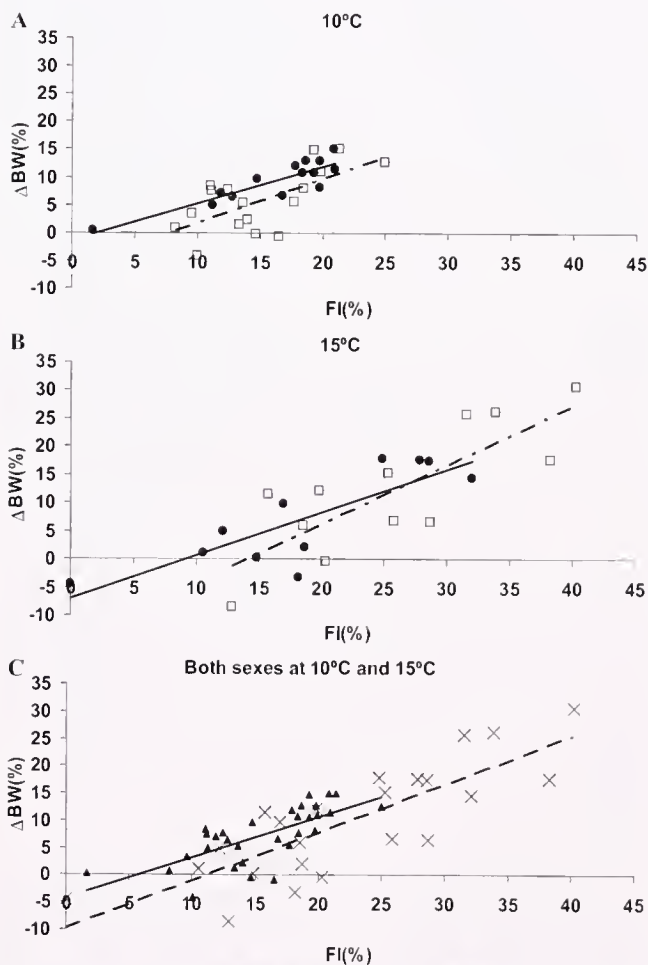

Figure 2. Growth [$\Delta BW(\%)$] versus food intake [$FI(\%)$] as a percentages of body weight measured each 10 days over 30 days period in males (●, solid line) and females (□, dash line) immature of *O. tehueltchus* held at 10°C (A) and 15°C (B). Pooled data for immature octopuses by temperature levels at 15°C (×, dash line) and 10°C (▲, solid line) (C). Dash and solid lines represents the estimated curve for each treatment.

Figure 3. Growth [$\Delta BW(\%)$] versus food intake [$FI(\%)$] as a percentages of body weight measured each 10 days over 50 days period in both males (●) and females (□) mature of *O. tehueltchus* held at 10°C (A and B). Pooled data of males and females held at 10°C (C). Dash and solid lines represents the estimated curve for each treatment.

Comparison of GGE by Classical Statistical Methods

For immature octopus kept at 10°C and 15°C, direct comparison between confidence intervals at 95% indicated no significant difference in GGE mean values at different temperatures (Fig. 4). The t' Welch approximation test for disparate variances showed no differences in GGE mean values between immature and mature individuals kept both at 10°C ($P = 0.0939$).

Comparison of GGE Based on Growth Versus Food Intake Relationship

These are the results obtained using the relationship between growth and food intake as an alternative method to investigate differences in GGE under different treatment. From intercepts analysis (ANCOVA) for immature octopuses kept at 10°C and 15°C, difference between intercepts of two temperature levels was found ($P = 0.0326$), whereas no significant effect of sex was observed ($P = 0.3695$). These results allow inferring in the first place that immature individuals at 10°C showed a higher GGE than those at 15°C. Secondly, under a fixed temperature males and females invested in growth the same portion of ingested food. For mature octopuses kept at 10°C, either males or females invest in

growth-equivalent portions of food intake. From the intercept analysis a significant difference was detected between GGE of mature and immature octopuses kept at 10°C ($P = 0.0020$). This result indicates that at 10°C immature specimens were more effective in converting food in body growth than mature ones.

DISCUSSION

This study reported the effects of temperature, sexual maturity and sex on growth and food intake under laboratory conditions in the "Pulpito" *Octopus tehuatlensis*. In addition, an alternative method to investigate the influence of different treatments on gross growth efficiency was developed.

Within the normal range temperature adaptation of a cephalopod species, higher temperatures lead to greater food intake, with exceptions such as sepiolids (v Boletzky 1975). In addition, if food is not limiting, temperature is a key factor influencing cephalopod growth rates, particularly during the early growth phase (Forsythe

Figure 4. Gross growth efficiency (GGE) for immature *O. tehuatlensis* held at 10°C and 15°C. Vertical bars show the confidence interval at 95%.

1993). In this study, immature specimens of *O. tehuatlensis* displayed higher daily feeding and instantaneous growth rates at 15°C than 10°C. These results are in accordance with previous experimental cephalopod studies (e.g., *O. briareus*; Robson 1929, Borer 1971, *O. vulgaris*; Mangold & Boletzky 1973 and Aguado & García 2002, *Eledone moschata*; Lamarek 1798, Mangold & Boucher-Rodoni 1973, *O. tetricus*; Joll 1977, *O. ocellatus* Gray 1849, Segawa & Nomoto 2002).

A gradual daily feeding rate reduction appears to be the general rule for an octopus nearing sexual maturity (Borer 1971, Van Heukelem 1976, Wodinsky 1978). This is in agreement with the present findings for *O. tehuatlensis*, where mature males and females showed lower daily feeding rates than immature specimens kept at the same temperature.

In immature specimens of *O. tehuatlensis* the sex appears to have had no effect on feeding and growth rates; in neither 10°C nor 15°C temperature water. Mature males kept at 10°C showed a G value equal to zero whereas mature females showed a significant positive G value. This finding implies that in mature octopuses sex would have an effect on growth. Ré (1989) found that in natural conditions, *O. tehuatlensis* males reach sexual maturity three months earlier than females. Therefore, by the time those specimens were collected, males were already into an advanced sexual maturity state than females, who still were in their sexual maturation process. Moreover, although mature males and females showed no differences between daily feeding rates, only females had measurable positive growth. Likely, the lack of measurable growth in mature males of *O. tehuatlensis* could be because of an effect of advanced age on growth process, which would allow a normal feeding activity with either low or none growth-tissue production. Similar results have been reported by Cortez et al. (1995) for *O. mimus* (Gould, 1852) collected from the Pacific waters of Chile.

For the present work, no statistically significant, sex-based differences were found among immature animals in terms of instantaneous growth rates or daily feeding rates. However, a slight tendency of instantaneous growth rates was observed to show slightly higher values in males at 10°C but higher in females at 15°C. Similarly, Forsythe and Hanlon (1988) observed higher growth in *O. bimaculoides* (Pickford/McConnaughey, 1949) males at 18°C but higher in females at 23°C. Considering that males of *O. tehuatlensis* reach the sexual maturity approximately 3 mo earlier than females, this tendency in data could indicate an interaction

between sex and temperature on instantaneous growth rates and daily feeding rates for immature specimens. Thus, in colder periods, immature males should show significantly higher daily feeding rates, instantaneous growth rates and gross growth efficiencies than females.

For all treatments performed in the present study, the relationship between growth and food intake was linear. Estimated values of body weight lost and maintenance level in immature octopuses at 15°C were higher than those at 10°C. In mature individuals kept at 10°C these values showed no differences between sexes. Immature individuals showed constant partial growth efficiency over sexes and temperature treatments. Because of the difference, experimental and biological conditions (e.g., temperature level and body weight) and comparisons among species become an arduous task. For individuals of *O. tetricus* kept at a mean of 20°C, a graphic estimation from the linear relationship between growth and food intake a maintenance level of 1% BW day⁻¹ and a daily body weight lost of 0.7% were obtained. The value of partial growth efficiency was estimated as 82.8% after the maintenance requirements have been satisfied (Joll 1977). For *O. cyanea* and *O. maya* reared at 25°C, the best fit to explain the relationship between growth and food intake was linear (Van Heukelem 1976, 1987). For both species the least square method indicated a maintenance level of 1.8% BW day⁻¹ and a body weight lost of 1.01% BW per day with a partial growth efficiency of 70% (Van Heukelem 1976, 1987). From present data and literature cited, an increase in temperature yielded higher maintenance level and daily body weight lost, whereas the linear form of the relationship between growth and food intake remained unalterable.

Gross growth efficiency (GGE) estimated for immature *O. tehuelchus* held at 10°C (GGE = 52%) are among the highest reported in the literature. Nixon (1966) observed a GGE value of 46% for *O. vulgaris*. Research on *O. maya* and *O. cyanea* held at 25°C produced GGE means values of 39.5% and 38.3% respectively, although for the estimated values of GGE mature octopuses data were not included (Van Heukelem 1976). Joll (1977) found that *O. tetricus* kept between 16.5°C and 24.2°C possess a GGE mean value of 46.8%. A lower GGE value of 37% was found for *Eledone moschata* held at 15°C (Mangold 1987). Daly and Peck (2000), recorded for three individuals of the Antarctic octopus *Pareledone charcoti* (Joubin, 1905) at 0°C under laboratory conditions a GGE mean value of 32%.

Gross growth efficiency declines when old males and maturing females of *O. maya* and *O. cyanea* decrease food intake (Van Heukelem 1976). Moreover, O'Dor and Wells (1978) pointed out that sexual maturation in females involves different needs for nutrients and energy, because females have higher reproductive costs

for egg formation. When the t'Welch approximation test for disparate variances was used to compare GGE means between mature and immature specimens kept at 10°C, no significant difference was detected. Contrariwise, the alternative method based on the comparison between intercepts was able to detect a significant difference between GGE of immature and mature octopuses. Agreeing to Wells et al. (1983) and O'Dor et al. (1983) findings for *O. vulgaris*, *O. tehuelchus* showed in growth and food intake a high individual variability. Likely, this variation in GGE, which produces great variance value, can explain why t'Welch approximation test failed to detect differences between GGE. Furthermore, the low daily feeding rate and high maintenance level observed in mature specimens of *O. tehuelchus* could yield a lower GGE than immature octopuses kept at 10°C.

The confidence intervals at 95% comparison indicated no difference between GGE of immature specimens kept at 10°C and 15°C. Contrariwise, the alternative method based on the comparison between intercepts indicated that immature specimens held at a 10°C showed higher GGE than individuals kept at 15°C. Mangold and v Boletzky (1973) for individuals of *O. vulgaris* feed *ad libitum* and held at 10°C, 15°C and 20°C recorded gross growth efficiencies mean values of 56%, 55% and 48% respectively. Despite this, no statistics differences in GGE of *O. vulgaris* between temperature levels were reported. As it was observed in *O. tehuelchus*, *O. vulgaris* showed the highest GGE value at the lowest temperature treatment. Aguado Giménez and García García (2002) by mean of a multiple regression analysis observed in *O. vulgaris* that GGE increased from 13°C to an optimal temperature value at 16.5°C, after this point GGE decreased to zero at 23°C. As it was observed in *O. tehuelchus* and *O. vulgaris*, for the normal range of temperature for a species, gross growth efficiency is affected by temperature. In addition, in *O. tehuelchus* the sexual maturity has an effect on GGE. The results obtained in this work indicate that, whereas classic statistical tests failed to detect the effects of temperature and sexual maturity on GGE, the alternative method based on the growth versus food intake relationship was able to do it. The information obtained about the effect of temperature and sexual maturity on growth, food intake and gross growth efficiency of *O. tehuelchus* under laboratory conditions could be used to develop potential rearing techniques.

ABSTRACT The subcellular fractionation of the digestive gland cells of the common cuttlefish *Sepia officinalis* was performed to investigate the distribution of metals between organelles and cytosol and the different cytosolic fractions separated by gel-filtration chromatography. Total metal concentrations vary over 3 orders of magnitude, ranging from dwT for Pb to dwT for Zn. With the exception of Cd, Co, and Cu, metals were mostly bound to the organelles. Whereas no specific organelle compartment was found for Mn, Pb, and Zn, Fe was mainly associated with nucleus, brown body, and “boule” fraction (i.e., 52%) and 44% of the total Ag was contained in the lysosomal and mitochondria enriched fraction. The link of metals with hydrosoluble proteins in the cytosolic fraction was investigated at 254 and 280 nm. Direct relationship between cytosolic metal and metallothioneins could only be established for Ag and Cu, whereas Cd and Zn seem to mainly bind high (>70 kDa) and low (<4 kDa) molecular weight proteins.

KEY WORDS: cephalopod, metal, trace element, detoxification, metallothionein, chromatography, *Sepia officinalis*

INTRODUCTION

Exclusively marine organisms, cephalopods, are active predators found from polar to tropical ecosystems and from the shallow waters to very deep ocean environments. As well, they constitute a major food source for many top predators species (see the reviews by Clarke 1996, Croxall & Prince 1996, Smale 1996, Klages 1996). They therefore have a key role in many marine ecosystems and are also of increasing interest for worldwide fisheries (Amaratunga 1983, Rodhouse 1989). Despite such ecological and economical importance, metal; radioactive; and organic contaminants have globally been poorly studied in cephalopods.

Concerning metals, cephalopods concentrate several trace elements such as Ag, Cd, Cu, or Zn at sometimes very high concentrations (e.g., Martin & Flegal 1975, Miramand & Bentley 1992, Bustamante et al. 1998). Most of the studies reported the major role of the digestive gland in the bioaccumulation mechanisms, this organ suspected to have a key function in the metabolism of many metals in cephalopods (e.g., Miramand & Bentley 1992, Bustamante et al. 2002a, 2004). Thus, the digestive gland of cephalopods constitutes the main storage organ for essential (e.g., Co, Cu, Fe, and Zn) and non essential elements (e.g., Ag, Cd, Pb, and V) independently of the considered species and of its area of origin (e.g., Miramand & Guary 1980, Smith et al. 1984, Finger & Smith 1987, Miramand & Bentley 1992, Bustamante et al. 1998, 2002a, 2004, Miramand et al. 2006). Thus, around 70% to 98% of the whole body burden of metals could be readily stored in the digestive gland (Miramand & Bentley 1992, Bustamante et al. 2002b). This could result from the very long half-life of some elements like Cd and Co (Bustamante et al. 2002a, 2004) and/or to very efficient translocation processes from other organs and tissues to the digestive gland (e.g., Ag or Cs; Bustamante et al. 2004, 2006). In the case of Cd and Co for example, the residence time of the metal in the whole organism could be longer than the life span of the cephalopods, meaning that almost all the assimilated metal is definitively sequestered in the digestive gland (Bustamante et al.

2002a, 2004). In contrast to Cd and Co, Ag displays a faster turnover in cephalopods (Bustamante et al. 2004). Even the dissolved pathways are probably the main route for Ag accumulation in cephalopods, the digestive gland contains most of the whole body burdens of this metal (Miramand & Bentley 1992, Bustamante et al. 2000, 2004). This fact suggests that very efficient translocation processes allow the transfer of Ag from tissues and organs in contact with seawater to the digestive gland for detoxification purposes (Bustamante et al. 2004).

In both cases (i.e., metals directly stored for a long time in the digestive gland and metals having a peculiar tropism to this organ) the elevated concentrations reported on metal bioaccumulation in cephalopods suppose the occurrence of efficient storage and detoxification mechanisms to counteract the toxicity of metals (e.g., Simkiss & Taylor 1982, Phillips & Rainbow 1989). Detoxification mechanisms of marine invertebrates mainly involve the precipitation or co precipitation of metals on amorphous granules and the binding on proteins, which can be nonspecific (e.g., transferrin, ferritin) or specific to one or more metals (e.g., vanabins, metallothioneins [Durand et al. 2002, Ueki et al. 2003]). One well-known detoxification strategy involving proteins is the binding of some trace metals to metallothioneins (MTs), which play a role in the homeostasis of the essential metals Cu and Zn, but are induced by various other metals (i.e., Ag, Cd, and Hg) (Engel & Brouwer 1989, Cosson et al. 1991, George & Olsson 1994). Thus, MTs are considered to be involved in Ag, Cd, and Hg detoxification (Dallinger 1993, 1995, Roesijadi 1992, 1996, Viarengo & Nott 1993). In cephalopods, association of MT with metals in the digestive gland seems to mainly concern Cu and, to a lesser extent, Cd and Zn (Tanaka et al. 1983, Finger & Smith 1987). In the digestive gland, most of Cd and Zn appear to be bound to other cytosolic proteins than to MTs (Tanaka et al. 1983, Finger & Smith 1987, Castillo et al. 1990).

Considering the elevated metal concentrations occurring naturally in the digestive gland of cephalopods, the aim of our study was to investigate the metal distribution between the different organelles and the cytosol and to provide insight on the implication of hydrophilic proteins such as MTs in the detoxification mecha-

nisms. The common cuttlefish *Sepia officinalis* was selected as an experimental model, and the subcellular distribution of various metals, Ag, Cd, Co, Cu, Fe, Mn, Pb, and Zn, were considered in mature male individuals. Finally, the cytosolic fraction obtained was chromatographed to determine the association of the different metals to the hydrophilic proteins.

MATERIALS AND METHODS

Biological Material

Male mature common cuttlefish were caught in the Bay of Seine (French coast of the English Channel) and kept alive at the most two days in outflow tanks. Animals belonging to the same age class, from the same sex and sexual maturity state were selected to minimize the biological variability ($n = 4$, total weight 785 ± 84 g). Prior to the experimentation, cuttlefish were anaesthetized in seawater containing 2% ethanol and rapidly dissected. The digestive gland was carefully removed, weighed ($n = 4$, 37 ± 10 g), and prepared for direct heavy metal analysis and subcellular fractionation.

Subcellular Fractionation

Aliquots ranging from 1–2 g of each individual's digestive gland were homogenized with a mortar and pestle on ice with 4 volumes of a 20-mM TRIS-HCl, 0.25-M sucrose buffer (Tanaka et al. 1983), at pH 8.6. The homogenates were successively centrifuged at 600g for 10 min, 10,000g for 10 min and 100,000g for 60 min at 4°C in a Beckman LE-70 ultracentrifuge. This procedure giving six different fractions is summarized in Figure 1. Each pellet was collected to determine the metal concentrations in the membranes, nuclei, "boules" (which are considered as heterolysosomes and heterophagosomes involved in intracellular digestion of cephalopods [Boucaud-Camou 1976, Boucaud-Camou & Yim

1980]) and brown bodies fraction, the mitochondrial and lysosomal fraction, and the microsomal fraction. The accuracy of the sequential separation was controlled by Transmission Electronic Microscopy after fixation in 4% glutaraldehyde and postfixation with osmium tetroxide in 0.4 M cacodylate buffer at pH 7.3. The particle-free supernatant fraction (cytosol) was removed for heavy metal analysis and for gel filtration chromatography.

Gel-filtration Chromatography

Prior to the gel filtration chromatography, total proteins were quantified in the collected cytosol following Lowry et al. (1951). Then, 2 mL of this fraction were chromatographed on a Sephadex G-75 superfine (16×800 mm) column (Pharmacia) equilibrated and eluted with 20 mM Tris-HCl buffer, pH 8.6 at 4°C, containing 50 mM NaCl and 3 mM NaN_3 . The column was maintained at 4°C, and the samples were collected as 4 mL fractions. The UV absorbance of the eluate was measured at 254 and 280 nm with a U-1100 Hitachi spectrophotometer. In each eluted fraction, the heavy metal concentrations were also determined. The column was calibrated for molecular weight estimations with Ovalbumine (43 kDa), Chymotrypsin (25 kDa), Ribonuclease (13.7 kDa), and Glucagon (3.5 kDa) as standard markers. We also used equine renal metallothionein (13.4 kDa, Kojima et al. 1976) to identify the fractions containing MTs.

Metal Analyses

Samples of the digestive gland were previously dried at 80°C to constant weight prior to analysis. The dried digestive gland samples, the pellets, and the particle free supernatants resulting from the subcellular separation, and the different fractions separated by gel chromatography were digested with 5 mL of 14 N ultrapure HNO_3 at 100°C during 3 days. After evaporation of the acid, the residues were taken up in 5 mL 0.3 N HNO_3 and analyzed for Ag, Cd, Co, Cu, Fe, Mn, Pb, and Zn by flame and graphite furnace atomic absorption spectrophotometry with a Zeeman Hitachi model 180–70.

Quality control was assessed by heavy metal analyses in blanks and reference materials. Thus, Orchard-Leaves (National Bureau of Standards) and MA-A-2 fish flesh standard (IAEA) were treated and analyzed in the same way as the samples. Our results for the standard reference materials were in good agreement with the certified values (Table 1). The detection limits were ($\mu\text{g}\cdot\text{g}^{-1}$ dry weight): 0.004 (Cd), 0.02 (Ag), 0.1 (Co, Mn, Pb), 0.5 (Cu, V, and Zn), and 2.5 (Fe). Results are also expressed in micrograms per gram of the dry tissue weight ($\mu\text{g}\cdot\text{g}^{-1}$ dwt).

RESULTS

Metal Concentrations

The concentrations of Ag, Cd, Co, Cu, Fe, Mn, Pb, and Zn are shown in Figure 2. Among the analyzed metals Zn is the most concentrated, reaching up to $600 \mu\text{g}\cdot\text{g}^{-1}$ dwt, followed by Fe ($424 \pm 142 \mu\text{g}\cdot\text{g}^{-1}$ dwt) and Cu ($362 \pm 114 \mu\text{g}\cdot\text{g}^{-1}$ dwt). All other elements displayed far lower concentrations (i.e., ranging from $2.2 \mu\text{g}\cdot\text{g}^{-1}$ dwt) for Pb to $13.6 \mu\text{g}\cdot\text{g}^{-1}$ dwt for Cd.

Subcellular Distribution

The partitioning of metals among the (1) nuclei and brown bodies; (2) lysosomes and mitochondria; (3) microsomes; and (4) soluble cytosolic fraction is presented in Table 2. Most of the Cd, Co, and Cu were associated with hydrosoluble cytosolic com-

(): recommended value

pounds whereas Ag, Fe, Mn, Pb, and Zn were mostly bound to the organelles. Fe is mainly associated with the nuclei and brown bodies (52%), and 44% of the total Ag is contained in the lysosomal and mitochondria enriched fraction. It is noteworthy that Co, Cu, Pb, and Zn are equivalently distributed in each pellet (Table 2).

Metal Associated With Proteins

Chromatographic Sephadex G-75 elution profiles of the absorbance at 254 and 280 nm obtained for cytosol from the digestive gland of *Sepia officinalis* were used to determine the metal concentrations ($\text{mg}\cdot\text{L}^{-1}$) in the collected fractions containing the proteins separated by their molecular weight (Fig. 3). A first peak centered on fraction 11 corresponds to the void volume (macromolecules larger than 70 kDa, such as hemocyanin), and a second peak between fractions 40 and 44 indicates a particular richness in small proteins and polypeptides (4 kDa and less). MTs used for calibration fell in fraction 26 with an elevated 254/280 nm absorbance ratio (equal to 16). All metals were associated with high and low molecular weight proteins (>70 kDa and lower than 4 kDa, respectively) except Ag, which was not detectable in the small protein fraction. Intermediate proteins ranging from 10–20 kDa did not contain detectable amounts of Fe and Mn. Ag and Cu were the only metals showing a peak in the fraction 26 region among those expected to bind MTs (Ag, Cd, Cu, and Zn). Cd and Zn displayed

a very similar distribution with a major fraction associated with high molecular weight proteins for both metals.

DISCUSSION

The metal concentrations measured in the digestive gland of male adult cuttlefish from our study globally fell within the range of values reported for *Sepia officinalis* from the English Channel (Miramand & Bentley 1992), the Bay of Biscay (Schippe & Hevert 1978, Bustamante 1998, Bustamante et al. 1998), and the Mediterranean (Bustamante et al. 2002a). Although globally poorly documented, metal concentrations in cephalopods have received increasing interest as these molluscs play a major role as predators and food items in marine ecosystems. The central role of the digestive gland in metal bioaccumulation has been highlighted many times, particularly for toxic metals such as Ag and Cd (e.g., Martin & Flegal 1975, Miramand & Bentley 1992, Bustamante et al. 2002a, 2004), but the detoxification processes occurring in this organ remain poorly understood (Bustamante et al. 2002b). Investigations on detoxification mechanisms have focused either on the subcellular distribution of metals between cytosol and organelles (Rocca 1969, Tanaka et al. 1983, Finger & Smith 1987, Bustamante et al. 2002b, Craig & Overnell 2003), the involvement of hydrosoluble proteins in the binding of metals (see also Declerq et al. 1978, Ueda et al. 1985, Castillo et al. 1990, Castillo & Maita 1991) or on the histochemical and microanalytical localization of metals within the digestive gland cells (Schippe & Hevert 1978, Martoja & Marcaillou 1993). Moreover, the subcellular distribution of metals mainly concerned Cd, Cu, and Zn (i.e., Rocca 1969, Declerq et al. 1978, Tanaka et al. 1983, Ueda et al. 1985, Finger & Smith 1987, Castillo et al. 1990, Castillo & Maita 1991, Bustamante et al. 2002b, Craig & Overnell 2003), but very limited information is available for other elements. To the best of our knowledge, the studies of Tanaka et al. (1983) and Finger & Smith (1987) are the only ones providing data on other metals (i.e., Ag and Fe and ^{210}Po , respectively). The few studies on metal detoxification in cephalopods have considered various models like cuttlefishes (Declerq et al. 1978, Schippe & Hevert 1978, Martoja & Marcaillou 1993, Bustamante et al. 2002b), squids (Tanaka et al. 1983, Finger & Smith 1987, Castillo et al. 1990, Castillo & Maita 1991, Bustamante et al. 2002b), and octopuses (Rocca 1969, Ueda et al. 1985, Bustamante et al. 2002b). Consequently, results are often different between authors and sometimes contradictory. Therefore, there is a need to provide more information on the subcellular distribution of heavy metals in general and on poorly or not yet studied elements, also highly concentrated in the digestive gland of cephalopods. In this respect, our study provides the first

insight about the subcellular distribution of Co, Mn, and Pb in cephalopods.

Our study of metal distribution between the insoluble (membranes and organelles) and soluble (cytosol) fractions of the digestive gland leads to the conclusion that metals can be separated between those mainly associated with the hydrosoluble compounds Cd, Co, and Cu and those mainly associated with the organelles Ag, Fe, Mn, Pb, and Zn. This shift does not therefore correspond to the essential or non-essential character of the metals but rather to the result of specific regulation/detoxification processes.

As already mentioned, the scarce information on the subcellular distribution of trace elements in cephalopods put forward that 50% to 90% of the Cd is usually found in the soluble fraction of the digestive gland of cephalopod from the field (Finger & Smith 1987, Castillo et al. 1990, Bustamante et al. 2002b), even if the squid *Todarodes pacificus* does not follow this trend with only 26% ± 3% of the metal being present under a soluble form (Tanaka et al. 1983). Our results for *S. officinalis* are consistent with this

general trend (Table 2), suggesting the presence of mechanisms of detoxification of Cd involving soluble proteins. The presence of Cd detoxification mechanisms involving MTs was suspected when considering the chromatograms of metalloproteins from the digestive gland of the squids *Nototodarous gouldi*, *Todarodes pacificus*, and *Ommastrephes bartrami* from the Pacific Ocean (Tanaka et al. 1983, Finger & Smith 1987, Castillo & Maita 1991). Later, these proteins were quantified in various cephalopod species from the Northern Atlantic Ocean (Bustamante et al. 2002b). In *S. officinalis* from our study, cytosolic Cd was mainly associated with high molecular weight proteins, and MTs seem to have a minor role in the binding of this metal (Fig. 3). This result is in accordance with previous reported data for other cephalopod species. For example, most of the cytosolic Cd in the digestive gland of the squids *T. pacificus* and *Onychoteuthis borealojaponica* was bound to proteins weighing more than 70 kDa (Tanaka et al. 1983, Castillo et al. 1990). Only a small part of the soluble Cd was bound to low molecular weight proteins (<3 kDa) or to proteins of similar size to MT (10 kDa to 16 kDa). Moreover, Finger & Smith (1987) have

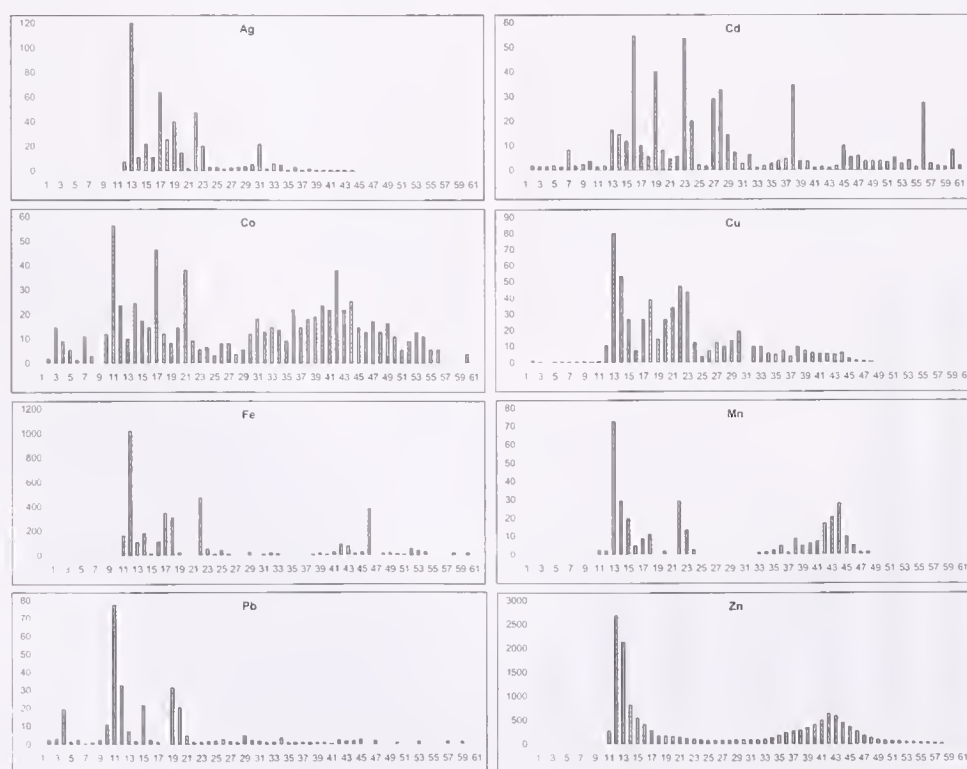

Figure 3. Metal profiles ($\mu\text{g.L}^{-1}$) after Sephadex G-75 gel chromatography of the cytosolic fractions of *Sepia officinalis* digestive gland.

also reported the occurrence of Cd-binding proteins with a high molecular weight (≥ 70 kDa) in the digestive gland of the squid *N. gouldi*.

Similarly to Cd, Cu has been mainly found in the cytosol of the digestive gland cells of the squids *N. gouldi* ($78 \pm 10\%$, Finger & Smith 1987) and *T. pacificus* ($63 \pm 5\%$, Tanaka et al. 1983) but poorly associated with hydrosoluble compounds in the squid *Loligo forbesi* (35%, Craig & Overnell 2003) and in the octopus *Octopus vulgaris* ($28 \pm 17\%$, Rocca 1969). The presence of high Cu concentrations in the digestive gland cells of *S. officinalis* has been revealed histochemically in specific structures called "spherules" (Martoja & Marcaillou 1993). These authors suggested that these metal-rich spherules would be made of complexed metallothionein-like proteins and would explain the high concentrations of Cu within the digestive gland. However, the presence of such structures has not been confirmed by other studies (Boucaud-Camou & Boucher-Rodoni 1983), and our results are not in accordance with such a hypothesis. Because of their size (i.e., several μm), such structures would be expected to sedimentate in the first or the second pellet fraction, containing in fact a low proportion of the total Cu (Table 2). In *S. officinalis* Cu was mainly cytosolic, a main pool corresponding to high weight proteins that might contain hemocyanin molecules (Taylor & Anstiss 1999). However, Cu also appears to be bound to MT proteins, and to a lower extent, small size proteins and peptides (Fig. 3).

To the best of our knowledge, no data on Co subcellular distribution in the digestive gland of cephalopod have been published to date. In *S. officinalis*, 64% of this metal was associated with the cytosolic fraction, which is similar to the results reported for the Bivalves *Chlamys varia* (76%), *Gafrarium tumidum* (79%), and *Isognomon isognomon* (65%) in their digestive glands (Bustamante & Miramand 2005, Météan et al. 2005). Low molecular weight proteins seem to have a major importance in binding Co (Fig. 3). This result is consistent with those of Nakahara et al. (1982) for *O. vulgaris* exposed to ^{60}Co by way of seawater, where the proteins involved in the binding of the radionuclide weighed less than 3 kDa.

The predominant distribution of Ag in the insoluble fraction (i.e., the noncytosolic fractions) could be caused by specific Ag storage/detoxification in the digestive gland. In various bivalves, Ag is trapped as nontoxic Ag_2S precipitates within their tissues (Ballan-Dufrançais et al. 1985, Martoja et al. 1989, Berthet et al. 1990, 1992) and is mainly found associated with the organelle subcellular fraction (e.g., Bustamante & Miramand 2005). This mechanism of sequestration would therefore inhibit the potentially deleterious effects of the toxic Ag, which is highly accumulated in the digestive gland of cephalopods (Martin & Flegel 1975, Miramand & Bentley, 1992). Specifically, the lysosomal and mitochondrial fraction appears to play a major role in the binding of Ag (Table 2). Our results concerning Ag are opposite to those of Tanaka et al. (1983) for the squid *T. pacificus* for which $64 \pm 4\%$ of the metal was reported to be soluble and associated with small proteins (< 3 kDa). The reasons of such a totally contrary result are difficult to identify because various biological and environmental factors could modify the subcellular distribution of a single metal within a group or a species, such as the phylogeny, the main pathway of incorporation (seawater vs. food), the level of the metal accumulated, etc (e.g., Ueda et al. 1985, Bustamante et al. 2002b). This clearly points out the need to give light on the issue of Ag subcellular distribution using a wide range of cephalopod species and controlled experimental conditions. Within the cytosolic frac-

tion, Ag was mainly bound to high molecular weight proteins and to a lower extent to MTs.

Similarly to Ag, Pb has no biological functions. In the digestive gland of *S. officinalis*, most of this metal was found in the organelles (62%). In the digestive gland of the scallop *C. varia*, Pb was also mainly bound to organelles (i.e., 66% of the total metal burden [Bustamante & Miramand 2005]). Similarly, in *Mytilus galloprovincialis* and *Modiolus modiolus*, Pb was mainly associated with the fraction containing nuclei, cellular debris, and insoluble salts (Julshamm & Andersen 1983, Regoli & Orlando 1994). In these Bivalves, Pb is accumulated by endocytosis and precipitate as sulphur or phosphate salts inside the digestive cells (Coombs & George 1978) as well as in the extracellular compartments (Schulz-Baldes 1978). Lysosomes are deeply involved in the detoxification of Pb and lead to the formation of Pb salts representing the final stage of the lysosomal detoxification process (Simkiss 1977). In *S. officinalis* no specific affinity among the different fractions has been shown (Table 2), suggesting that such a detoxification process is relatively limited, likely to be caused by low Pb concentrations found in this species.

The subcellular distribution of Fe in *S. officinalis* with 96% of the metal being bound to organelles, can only be compared with the 86% reported for *T. pacificus* (Tanaka et al. 1983). However, the distribution among the organelle fraction is clearly different as in the cuttlefish 52% was bound to the nuclei fraction whereas in the squid, 42% was bound to the microsome fraction. In Bivalves such as mussels or clams, Fe is also primarily associated with the nuclei fraction (Julshamm & Andersen 1983, Sullivan et al. 1988, Regoli & Orlando 1994). In these molluscs, Mn has a similar subcellular distribution as Fe, which is actually not the case for cephalopods (Table 2). This difference in the distribution of Fe and Mn between the organelles could be caused by the difference in the diet between carnivorous cephalopods and suspending or deposit feeder Bivalves. Indeed, Bivalves could ingest suspended/deposited material enriched in Fe and Mn hydroxide particules (e.g., Bryan & Uysal 1978). Within the cytosolic fraction, Mn and Fe are the only elements not associated with MTs (Fig. 3).

CONCLUSION

The subcellular distribution of heavy metals clearly varies depending on the considered element. For essential and toxic metals, the sequestration in either the organelles or the cytosolic proteins could lead to specific accumulation. In this context, it is particularly striking that the different detoxification mechanisms for toxic Ag (mainly insoluble) and Cd (largely soluble) lead to their bioaccumulation at relatively high concentrations in the digestive gland of *S. officinalis*. In our conditions, a direct relationship between cytosolic metal and MT could only be established for Ag and Cu, whereas Cd and Zn seem to mainly bind high (> 70 kDa) and low (< 4 kDa) molecular weight proteins. Further studies should focus on the induction of MTs by the different metals inducing it synthesis in other invertebrates (i.e., Ag, Cd, Cu, Hg, and Zn) in controlled conditions to determine the dynamic of the detoxification processes in cephalopods.

¹Centro Interdisciplinario de Ciencias Marinas-Instituto Politécnico Nacional, A.P. 592, La Paz, B.C.S., México; ²Centro de Investigaciones Biológicas del noroeste, A.P. 128, La Paz, B.C.S., México

ABSTRACT Fifty-two ovigerous females of *Cancer johngarthi* were caught from the Baja California Peninsula's western coast, Mexico. Carapace length, carapace width and total weight of each specimen were registered. Fecundity estimates were obtained from the wet weight of eggs in each organism. Mean fecundity was 765,227 eggs, corresponding to a mean carapace width of 117 mm, and the mean relative fecundity was 4,305 eggs per gram of female body weight. Fecundity data (F) were fitted in relation to carapace width (CW) to the power model $F = 0.84CW^{2.87}$, $R^2 = 0.52$. *C. johngarthi* has a high population renewal capacity compared with other larger species like *Maiopsis panamensis*, which produces between 351,000 and 1,162,668 eggs, and *Stenocionops ovata*, which produces between 35,187 and 180,057 eggs; in both species, the relative fecundity is lower than 1,000 eggs per gram of female body weight.

KEY WORDS: *Cancer johngarthi*, fecundity, Baja California Peninsula

INTRODUCTION

Cancer johngarthi is a crab belonging to the Cancridae family, distributed from Guadalupe island, Mexico (29°N, 118°W) to Panama bay (7°N) (Carvacho 1989). This species is commercially important because of the flavor and texture of chelae meat, mainly from males. In the Southern Baja California's western coast, as well as in the Gulf of California, this species lives in soft substrates, at depths in excess of 90 m, and aggregated in populations, which may sustain a fishery (Fiol-Ortiz & Cervantes-Díaz 1996, Sánchez-Ortiz et al. 1997, Carvacho 1989, Leija et al. 1992, Ramírez-Rodríguez et al. 2003). Based on these results, the Mexican government recently offered two commercial fishing permits for *C. johngarthi* using traps.

This implies the need to conduct detailed studies on the crab's biology and dynamics aimed at generating useful information for the design of fishery-management measures. For the previously mentioned, the main objective of this work is to produce fecundity estimates for *C. johngarthi*, of particular interest because of its relationship with the population renewal capacity of this species in the study area (García-Montes et al. 1987).

MATERIALS AND METHODS

In January 2003, *C. johngarthi* specimens were caught from the Southern Baja California Peninsula's western zone (24°45' to 25°10'N; 112°31' to 112°44'W and 23°34' to 23°52' N; 111°04' to 111°04' W, Fig. 1). The capture was conducted using a 25-m long fishing ship with a net capacity of 130 t, adapted to operate conical traps measuring 150 cm × 75 cm × 65 cm, with a plastic-coated steel frame and baited with sardine at a depth between 73 and 300 m (Ramírez-Rodríguez et al. 2003).

Fecundity was determined from the wet weight of eggs in each ovigerous mass. The number of eggs in three subsamples of 0.02 g each was counted using a stereomicroscope. Individual fecundity data were obtained by extrapolating the number of eggs in each in the three subsamples to the total weight of the egg mass in each female, and then the mean per female fecundity and the standard deviation were calculated. For each specimen, fecundity data were

adjusted in relation to carapace width (CW). CW was defined by the greatest straight-line distance (excluding lateral spines) across the carapace and chelae width and carapace length (CL) was defined by the line midway between the eyes to the midpoint of the posterior margin of the carapace. Also, the relative fecundity was calculated for each female as the number of eggs per gram of female body weight.

RESULTS

Of the three thousand eight hundred and thirty-six organisms sampled, 3,362 were males (87.6%) and 473 females (12.4%), of which 52 were ovigerous. The sex rate for the total sample was 1M:0.14F and significantly deviates from the 1:1 rate. Male size ranged from 98 mm to 176 mm in CW, with a mean of 146 mm ± 11 mm, whereas females measured 87–153 mm in CW, with a mean of 122 mm ± 9 mm.

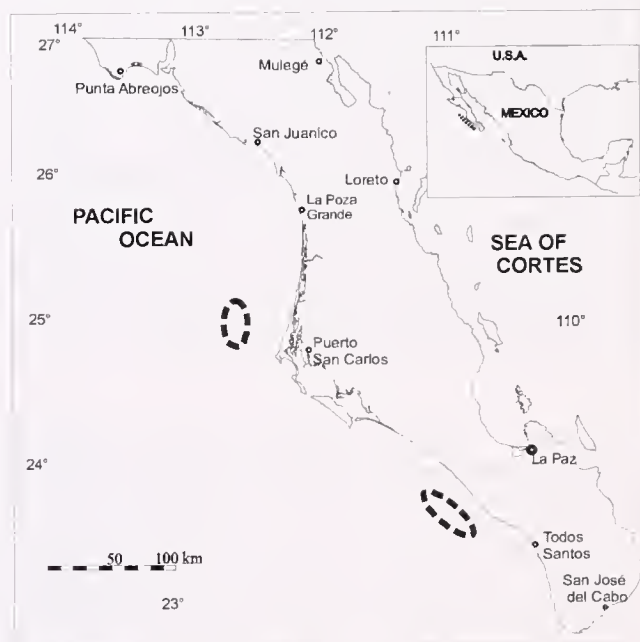

Figure 1. Baja California Peninsula's western coast. Sampling area.

*Corresponding author. E-mail: mvillale@ipn.mx

Figure 2. Potential relationship between CW and partial fecundity in *Cancer johngarthi*.

The 52 ovigerous females had a CW ranging between 98 and 131 mm, with a mean of $117 \text{ mm} \pm 8.4 \text{ mm}$; CL lied between 51 and 81 mm with a mean of $74 \text{ mm} \pm 6.9 \text{ mm}$. Fecundity varied between 381,441 and 1,517,668 eggs, with a mean of $765,227 \text{ eggs} \pm 233,415 \text{ eggs}$, whereas the relative fecundity ranged between 1,033 and 8,510 eggs/g with a mean of $4,305 \text{ eggs/g} \pm 1,402 \text{ eggs/g}$ of female body weight.

A power equation was fitted to fecundity data, with CW as the independent variable $r^2 = 0.52$ $\alpha = 0.05$, Fig. 2). The fit was poor in relation to CL ($r^2 = 0.31$), whereas it failed to display a defined relationship with respect to chelae length and body weight. Relative fecundity also failed to show a clear relationship with CW ($r^2 = 0.003$, Fig. 3).

DISCUSSION

According to the results of this work, *C. johngarthi* is a species with a high population renewal capacity, compared with other species of larger deep crabs like *Maiopsis panamensis*, which produces between 351,501 and 1,162,668 eggs, and *Stenocionops ovata*, which produces between 35,187 and 170,057 eggs; both species have a relative fecundity lower than 1,000 eggs per gram of female body weight (Villalejo-Fuerte et al. 1998, 1999).

In crustaceans, fecundity estimates derived from incubating eggs carried by females in their abdomen yield lower numbers compared with the estimates based on the number of intragonadal oocytes, because resorption of intraovarian oocytes during the maturation process occurs frequently. Additionally, many eggs fail when adhered to the pleopods at the time of spawning (Farmer 1974). Another factor that accounts for extraovarian fecundity estimates being lower than intraovarian ones is egg predation during incubation (Abelló & Sardá 1982); however, fecundity estimates obtained from incubating-egg data yield more precise information to determine the renewal capacity of a population.

Figure 3. Relationship between CW and relative fecundity in *Cancer johngarthi*.

The ovigerous masses analyzed were evenly colored, ranging from orange to dark brown, which suggests that the spawning period takes place rapidly with embryonic development occurring synchronously, so that no difference is evident, at least to the naked eye. Histological evidence suggest that *C. johngarthi* can produce more than one batch of eggs in a breeding cycle, as is the case of the deep-living Majids *Maiopsis panamensis* and *Stenocionops ovata* (Villalejo-Fuerte et al. 1998, 1999). This would account for the low determination coefficient of the potential fit to fecundity data, because the number of eggs produced in successive partial spawning events decreases, resulting in a less adequate relationship with the organism's morphometric variables, however there is no evidence in the fecundity-length data.

According to Leija et al. (1992), the reproduction process for *C. johngarthi* takes place in October and recruitment during March and September; however, in this work ovigerous females were caught in January, so that the spawning, fertilization and incubation of eggs is likely to occur during the fall and winter, with recruitment taking place in the spring. To prove the earlier discussed, it is required to conduct sampling across a whole annual cycle, recording the frequency of ovigerous females to confirm this information.

ABSTRACT Ten strains of *Artemia parthenogenetica* have been collected from inland salt lakes and coastal salterns in China. Ten diploid clones were selected from each *Artemia parthenogenetica* strain for analysis of the population genetic structure and genetic differentiation using inter simple sequence repeats (ISSR). One hundred and seventy fragments (100–2200 bp) were generated using 20 ISSR primers. A high level of genetic variation was found, with 96.47% polymorphic loci in total loci. The number of alleles (N_a), effective number of alleles (N_e) and Shannon information index (SI), the mean Nei's gene diversity (H), the average values of H_t , H_s , G_{st} for pairwise subpopulations and mean value of all 100 clones from 10 Chinese *Artemia parthenogenesis* strains were analyzed. The results showed that genetic structure of populations of *A. parthenogenetica* from China were complicated with high genetic diversity among the populations. Cluster analysis was then performed to create a dendrogram using the UPGMA method based on the Nei's genetic identity. The UPGMA dendrogram showed that 10 Chinese *Artemia parthenogenetica* strains can be significantly divided into three major groups (subpopulation): Liaoning, (PK and YK); Shandong and Hebei, (HH, TG, LN, WD, WZ and FC) and Qinghai and Xinjiang (GH and BLK).

KEY WORDS: *Artemia parthenogenetica*, ISSR, genetic structure, genetic differentiation

INTRODUCTION

Brineshrimp, *Artemia* (Crustacea Anostraca), are widely distributed in inland salt lakes and coastal salterns over the world. Populations of the genus *Artemia* were found in more than 600 habitats dispersed across the world (Van Stappen 2002). The genus *Artemia* comprises a complex of bisexual species defined by the criterion of reproductive isolation and of a large number of parthenogenetic populations under the binomen *A. parthenogenetica*, composed of diploid and polyploidy individuals for taxonomic convenience (Sun et al. 1999). The Morphological study (Triantaphyllidis et al. 1994), genetic variation (Zhang & King 1992) and evolution of most parthenogenetic *Artemia* populations have been examined by means of allozyme electrophoresis, karyotype, high repeat sequence (Abreu-Grobois & Beardmore 1980, 1982, 1983, 1991; Beardmore & Abreu-Grobois 1983, Badaracco et al. 1991, Bowen et al. 1988, Barigozzi, 1974, Barigozzi et al. 1987, Hou et al. 1993, 2000), molecular markers such as RAPD and AFLP (Camargo et al. 2002, Sun et al. 2000). In China, *A. parthenogenetica* is found in either saltworks along the coast of Bohai sea or salt lake from Qinghai, Xinjiang (Wang et al. 1991; Yang et al. 1995, 1996, Hou et al. 2000). The relationship with bisexual *Artemia* and expression of isozyme gene have been analyzed (Gao et al. 1994; Hou et al. 2003), but little is currently known about that population genetic structure and genetic differentiation of different geographic parthenogenetic *Artemia* strains in China.

Molecular genetic information has been increasingly used to detect the population genetic structure and genetic diversity among morphologically similar populations of a same species. Of the many molecular approaches available today, the simple inter sequence repeats (ISSR) technique is among the most sensitive. The ISSR technique had been successfully used to reveal population

genetic structure and relationship (Kantety et al. 1995, Nagaoka & Ogihara 1997, Martín & Sánchez-Yélamo 2000) and genetic diversity (Awasthi et al. 2004; Brantestam et al. 2004). The ISSR primer sequences are designed from microsatellite regions and the annealing temperatures used are higher than those used for RAPD markers, which have better reliability. Also, the technique does not require prior knowledge of DNA sequence for primer design, which is more practical (Wolfe et al. 1998).

In this study, the molecular marker of ISSR was used to help analyze the population genetic structure and genetic diversity of *Artemia parthenogenetica* in China. The Chinese *Artemia parthenogenetic* populations along the coastal of Bohai sea are all diploid (Pilla 1992, Triantaphyllidis et al. 1997) with the exception of Huanghua (Hebei Province) where a few tetraploid individuals appeared, and there are also a few triploid, tetraploid and pentaploid individuals that appeared in Balikan saltlake and Aibi saltlake in the Xinjiang autonomous region; therefore only diploid clones are being studied.

MATERIALS AND METHODS

Artemia cysts of 10 geographic strains of *A. parthenogenetica* were collected directly from different areas in China, followed by their code abbreviations (used hereafter), is as follows: Balikun, Xinjing Autonomous Region (BLK); Gahai, Qinghai Province (GH); Wudi, Shandong Province (WD); Yingkou, Liaoning Province (YK); Tanggu, Tianjin (TG); Luannan, Hebei Province (LN); Pikou, Liaoning Province (PK); Huanghua, Hebei Province (HH); Fengcheng, Shandong Province (FC); Wuzhi, Shandong Province (WZ) (Table 1).

The nauplii were hatched from the cysts of different strains according to the methods described by Sorgeloos et al. (1986). The nauplii were cultured for 15 days to adulthood in the laboratory, fed on *Dunaliella salina*, then 30 single individual clones were created from each strain according to the methods described by

Hou et al. (2000), and 300 clones were obtained from 10 strains. The ploidy of clones was examined using the methods described by Cai and Hou (1991) and Yang et al. (1996), 10 diploid clones were selected from 30 clones in each strain, and 100 clones were obtained from 10 strains. The individuals of 100 diploid clones were used for DNA extraction.

DNA Extraction

Artemia genomic DNA used for ISSR analysis was isolated as described by Sun (1999) with some modifications: (1) after removing the digestive tract, each individual was directly immersed in a 200- μ L solution (100 mM $^{-1}$ EDTA, 10 mM $^{-1}$ Tris-HCl), containing 25 μ L 10% SDS and 10 μ L 20 mg mL $^{-1}$ proteinase K; (2) the incubated temperature was increased to 60 $^{\circ}$; (3) non purified DNA was directly extracted and used to ISSR amplification. After isolation, DNA was stored in 10- μ L TE solution. DNA quality and quantity were determined by 0.8% agarose gel electrophoresis.

ISSR PCR Amplification

Twenty ISSR primers were synthesized from Saibaisheng Inc based on core repeats (Zietkiewicz et al. 1994), anchored either at the 5' or 3' end (Table 2). All ISSR primers were evaluated for their ability to produce polymorphic bands.

ISSR amplifications was performed by using the ISSR primers in a 20 μ L reaction volume containing 2.0 μ L \times 10 buffer, 1.25 μ L of 25 mM MgCl $_2$, 2 μ L of 10 mM dNTP, 1.0 μ L of primer at 10

pM, 5–10 ng DNA template, and 0.5 μ L of *Taq* DNA polymerase (Takara Inc) and 20 μ L water volume. An initial 5 min denaturation at 94 $^{\circ}$ C was followed by 45 cycles of 94 $^{\circ}$ C denaturation for 30 s, 52 $^{\circ}$ C annealing for 45 s, 72 $^{\circ}$ C extension for 2.0 min. Amplification cycles were followed by a final 7 min extension at 72 $^{\circ}$ C. Amplification was carried out with a PCR Express machine (ThermoHybaid, Needham Heights, MA). The size and quality of PCR products were determined on 2.0% agarose gels. Molecular weights were estimated using DL2000 DNA marker (Takara Inc).

Data Analysis

Data were scored in function of the presence (1) or absence (0) of every amplification product, and the data were entered into a data matrix. Based on data matrix of ISSR, Nei's (1978) genetic identity (*I*) (1978) and Nei's genetic distances (*D*) (1987) between geographical strains were analyzed. Measurements of diversity including gene diversity (*H*) at each locus; observed number of alleles (*N_a*); effective number of alleles (*N_e*) and Shannon information index (*SI*); gene differentiation (*G_{ST}*), according to McDermott and McDonald (1993), were estimated using the POPGENE 1.32 statistical package. Based on the matrix of genetic identity (Nei 1978) cluster analyses were performed using unweighted pair/group method with arithmetic averages (UPGMA) (Sneath & Sokal 1973). The dendrogram was constructed by software PHYLIP 3.5c neighbor and TreeView1.66.

RESULTS

Using 20 ISSR primers we detected 170 bands of which 164 were polymorphic (96.47%). The level of polymorphism for each primer is quite variable, ranging from 54.12 per cent (in GH strain) to 55.10 per cent (87.06) (in PKstrain). Band size ranged from 100–2200 bp. Representative ISSR fingerprints obtained with primer (AC) $_8$ T are shown in Figure 1.

Population Genetic Structure

Table 3 showed the number of polymorphic loci and percentage polymorphic loci, mean observed number of alleles (*N_a*), mean effective number of alleles (*N_e*), mean Nei's gene diversity (*H*) and mean Shannon's Information index (*I*) in the 100 clones from 10 Chinese *Artemia* parthenogenetic strains. The observed number of alleles (*N_a*) ranged from 1.8706 (PK) to 1.5412 (GH), mean value of *N_a* was 1.7571. Compared with *N_a*, the *N_e* values (effective number of alleles) were lower, which ranged from 1.2557 (GH) to 1.6219 (LN). The Nei's gene diversity (*H*) ranged from 0.1551(GH) to 0.3476 (LN), mean Nei's gene diversity was

YK	10	1.7588 ± 0.4291	1.5443 ± 0.3850	0.3041 ± 0.1977	0.4427 ± 0.2754	129 (75.84%)
PK	10	1.8706 ± 0.3366	1.6063 ± 0.3318	0.3443 ± 0.1645	0.5040 ± 0.2250	148 (87.06%)
BLK	10	1.7882 ± 0.4098	1.5556 ± 0.3510	0.3162 ± 0.1850	0.4616 ± 0.2603	134 (78.82%)
GH	10	1.5412 ± 0.4998	1.2557 ± 0.3350	0.1551 ± 0.1846	0.2398 ± 0.2645	92 (54.12%)
Mean	100	1.7571 ± 0.1000	1.5157 ± 0.1173	0.2925 ± 0.0620	0.4292 ± 0.0855	164 (96.47%)

* N_a = Observed number of alleles; N_e = Effective number of alleles [Kimura and Crow (1964)]; H = Nei's (1973) gene diversity; SI = Shannon's Information index [Lewontin (1972)]; [See Nei (1987) Molecular Evolutionary Genetics (p. 176–187)]

0.2925. Shannon's Information index (SI) estimated a measure of intrapopulation diversity, the highest value (0.5050) was found in the LN strain and the lowest value was 0.2398 in the GH strain, mean value was 0.4292. The Nei's genetic identity (I) and genetic distance (D) are examined for all pairwise comparisons between the subpopulations (Table 4). The genetic distances for all comparisons range from 0.0352 (between HH and TG) to 0.3353 (between YK and GH). The Nei's genetic identity among these 10 *Artemia* parthenogenetic strains (subpopulations) range from 0.7151(YK/GH) to 0.9654(TG/HH). The UPGMA dendrogram of Nei's genetic identity for 10 Chinese *Artemia* parthenogenetic strains showed that different geographic parthenogenetic strains were divided into 3 groups (subpopulation): Liaoning Province; Shandong and Hebei Province and Qinghai and Xinjiang (Fig. 2).

Genetic Diversity and Genetic Differentiation

Table 5 shows the total variation (H_t), the average variation within populations (H_s) and gene differentiation (G_{st}) for pairwise strains and mean value of H_t , H_s and G_{st} of all 100 clones from 10 Chinese *Artemia* parthenogenetic strains. The highest H_t value (0.3902) is found between LN and BLK strains, and the lowest value is 0.2639 between WZ and FC strains. The mean value of H_t from 100 clones was 0.3895, indicating that about 38.95 percent of genetic variation among the different strains. The H_s value is variable, ranges from 0.3459 (LN/PK) to 0.1853 (WZ/GH), with

the mean value of H_s 100 clones was 0.2925. The values of gene differentiation (G_{st}) of 100 clones from 10 Chinese *Artemia* parthenogenetic strains range from 0.3464 (WZ/GH) to 0.0674 (WZ/FC), the mean value was 0.2492. The regression line based on $\log_{10} G_{st}$ values and $\log_{10} Km$ (geographical distance) pairwise among 10 subpopulations of *Artemia parthenogenetica*, is plotted by SPSS software. There is a significant correlation of t -test of regression coefficient ($t = 7.7887$, $P = 0.0001$). The regression equation is $\text{Log}G_{st} = 0.2677\text{Log} Km - .5679$, $R^2 = 0.5909$.

DISCUSSION

ISSR has been successfully used to reveal genetic variation in silkworm (Pradeep et al. 2005), in aphids (Abbot, 2001) and in *Fenneropenaeus chinensis* shrimp (Wang & Kong, 2002), to characterize genome diversity (Yang et al. 1996), and to determine the origin of hybrids (Wolfe et al. 1998). The primers are anchored at their 3' end, to ensure that the annealing of the primer occurs only at the 3' or 5' end of the microsatellite motif, thus obviating internal priming and smear formation. The anchor also allows only a subset of the targeted inter-repeat regions to be amplified, thereby reducing the high number of PCR products expected from the priming of dinucleotide inter-repeat regions to a set of about 10–50 easily resolvable bands. Pattern complexity can be tailored by applying different primer lengths and sequences (Zietkiewicz et al. 1994). Based on its unique characters, the ISSR technique can

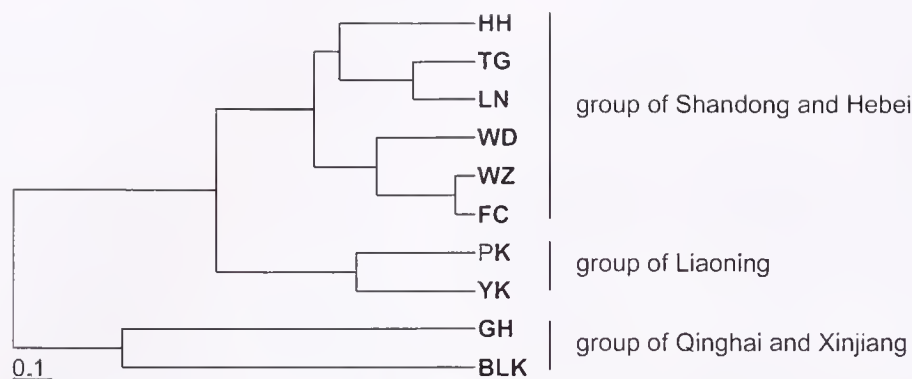

Figure 2. UPGMA dendrogram of Nei's genetic identity (*I*) for Chinese parthenogenetic *Artemia* strains. The 10 Chinese *Artemia parthenogenetica* strains can be significant divided into three major groups (subpopulation): Liaoning (PK and YK); Shandong and Hebei (HH, TG, LN, WD, WZ and FC) and Qinghai and Xinjiang (GH and BLK). For abbreviations of the different geographic *Artemia* strains, see Table 1.

detect more genetic loci than isozyme and has higher stability than RAPD. This is the first report of using ISSR markers in surveying genetic structure and differentiation in *Artemia parthenogenetica*. ISSR fingerprints clearly distinguished all the tested *Artemia parthenogenetica* populations. The experimental results show high genetic diversity and difference among 10 different geographic strains (subpopulation) of *A. parthenogenetica* in China. There are high proportions (96.47%) of polymorphic loci, indicating the higher-level variation in the 10 different geographic strains. Nascetti et al. (2003) and Hou et al. (1993) by isozymes and Sun et al. (2000) by AFLP and RAPD found high levels of genetic diversity, high levels of genetic variability and high proportions of polymorphic loci in parthenogenetic populations, although different molecular marker techniques were used in the experiments the conclusions were the same. Based on our experimental data earlier, we supported their opinions of high-level genetic diversity and high proportion of polymorphic loci in *Artemia parthenogenetica* populations. Nascetti et al. (2003) reported high levels of heterozygosity of *A. parthenogenetica* populations from Italy arranged from 0.135–0.185 by isozymes. In this study, because of limitation of the ISSRs technique, heterozygosity of different geographic populations was not calculated.

The UPGMA dendrogram based on Nei's genetic identity for Chinese *Artemia parthenogenetica* strains showed that different geographic parthenogenetic strains can be divided into three groups (subpopulation): Liaoning Province, group of Shandong and Hebei Province; Qinghai Province and Xinjiang Autonomous Region. Moreover, compared with the inland saltlake group of Qinghai and Xinjiang, the coastal groups, which included the groups of the Liaoning and Shandong and Hebei Province have a closer relationship. In agreement, the AFLP marker (Sun 1999) showed that *A. parthenogenetica* from inland and coastal origin, group into two different clusters, and allozyme analysis (Gao et al. 1994) also indicate that there is a significant difference between the populations from coastal China (Huanghua, Hebei province, and Dalian, Liaoning province) and from inland salt lakes (Xinjiang Autonomous Region). Hence, the parthenogenetic populations from inland salt lakes could have followed an evolutionary path that is different from that of the coastal parthenogenetic populations, or the large genetic differences possibly occur because of geographic isolation. To explore the reason for relationships among different strains, we introduce the parameter of *Gst* (Nei & Chakraborty 1973). *Gst*, which can be used to explain the population genetic differentiation, is equivalent to *Fst* (Wright, 1951) when there are only two alleles at a locus, and, in the case of

multiple alleles; *Gst* is equivalent to the weighted average of *Fst* for all alleles (Nei & Chakraborty 1973). In this study, we did not find statistics data of *Gst* value in other strains, therefore *Gst* was compared with *Fst* of different geographic strains. The *Gst* value (0.3464) is higher within distant geographic subpopulations (WZ/BLK), average value is 0.2492, implying a higher genetic differentiation among populations. The *Gst* values (0.036–0.3464) of *A. parthenogenetica* in China is higher than that of the Chinese bisexual populations of *Artemia* (*Fst*, 0.0024–0.1297) (Xin et al. 2000), which revealed that high differentiation level among *A. parthenogenetica* within population (clones) (24.92% of variation within population and 75.08% of variations among populations of *A. parthenogenetica*). The adverse surroundings conditions in habitats of *Artemia* populations (shortage of food, higher salinity, irregular temperature) could result in higher levels of genetic diversity, differentiation and polymorphic phenomena in *A. parthenogenetica* populations, and selection plays an important role in the processes (Bowen et al. 1988, Browne & Hoopes 1990, Lenz & Browne 1991, Browne 1992, Hou et al. 1993, Nascetti et al. 2003). Meanwhile, the different environmental conditions could be responsible for selective fixation in heterozygosity of many loci and for high genetic divergence observed between either diploid/polyploidy or polyploidy populations (Barigozzi 1974, Nascetti et al. 2003). Once heterozygosity originates, it could maintain through selective pressure caused by environmental conditions (Zhang & King 1992). Although the earlier-mentioned hypothesis is supported by experimental results of Nascetti et al. (2003), Hou et al. (1993) and Zhang and King (1992) the formation mechanism of high levels of genetic diversity of *A. parthenogenetica* needs to be explored further.

Population genetic structure and *Gst* values can be changed by migration among individuals of different populations. *Artemia* cysts were suited for passive dispersal by wind, waterfowl or man (Persoone & Sorgeloos 1980), this passive migration may change gene diversity (*Gst* and *Fst*) and gene flow (*Nm*). In this study, the reasons for causing high-level genetic variations in population could be migration. We estimated the relationship *Gst* (intrapopulation genetic variations) and geographic distance (Fig. 3). Figure 3 shows, a clear tendency for higher *Gst* value with far geographical distance (*Km*) and revealed high genetic differentiations with far geographical distance. The Cause for high level genetic differentiation was that geographic distance plays an important role in *Artemia* cysts dispersal, cysts were difficult to disperse alone in long distances. The genetic differentiation (*Gst*) levels among these subpopulations raise with the increasing geographical dis-

The number of polymorphic loci is : 164

The percentage of polymorphic loci is : 96.47

Mean values of *Ht*, *Hs* and *Gst* of 100 clones from 10 chinese *Artemia parthenogenetica* populations [See Nei (1987) Molecular Evolutionary Genetics (p. 187–192)]

Figure 3. Regression line based on $\log_{10} G_{st}$ values and $\log_{10} K_m$ (geographical distance) pairwise between 10 subpopulations of *Artemia parthenogenetica*. There is a significant correlation of *t*-test of regression coefficient ($t = 7.7887$, $P = 0.0001$). The regression equation is $\text{LogGst} = 0.2677\text{Log Km} - 1.5679$, $R^2 = 0.5909$

tance, therefore the high *Gst* levels may be results of genetic isolation by a geographical distance barrier. Conversely, WZ, FC and WD have a short geographic distance, and individuals of different populations may exchange very frequently by migration. *Gst* values of WZ, FC and WD were low, which indicates the presence of low level genetic differentiations among these subpopulations. Although the gene flow could not be estimated among *Artemia parthenogenetica* strains, genetic differentiations among different strains may be affected by a geographical isolation barrier and migrating by birds, wind, workers of salt works and others (Andy et al. 2005; Browne et al. 1993).

In recent years, a large amount of male individuals (40% and above) were found in *A. parthenogenetica* from the Chinese coastal salt works, it was believed that this was caused by ecological invasion of *A. franciscana* or *A. sinica*, because cysts of *A. franciscana* or *A. sinica* were introduced into these salterns for aquaculture. The samples in this study were collected before ecological invasion occurred, so it is important to know basal data of the population genetic structure and clone diversity of *A. parthenogenetica* from China. Taxonomic status of invader and population genetic structure need to be studied further.

ACKNOWLEDGMENTS

The authors thank Prof. Cai Hanjun for providing us with cysts of the Wuzi, Wudi and Huanghua strains and Sarah E. James Roger McMurray, Holly E. Snow and Wan-Xi Yang for their critical reading of this manuscript. This project was supported by The National Nature Science Foundation of China (No.30271035, 39870118).

THE GROWTH OF JUVENILE CHINESE SHRIMP, *FENNEROPENAEUS CHINENSIS* OSBECK, AT CONSTANT AND DIEL FLUCTUATING TEMPERATURES

XIANGLI TIAN, SHUANGLIN DONG,* FANG WANG AND LIXIN WU

The Key Laboratory of Mariculture, Ministry of Education Fisheries College, Ocean University of China, Qingdao, 266003, People's Republic of China

ABSTRACT The growth, food consumption, food conversion efficiency and apparent digestibility coefficient of juvenile Chinese shrimp, *Fenneropenaeus chinensis* Osbeck (body weight 0.36 ± 0.04 g) were examined under different temperature regimes. The animals were subjected to 6 constant temperatures of 18°C, 22°C, 25°C, 28°C, 31°C and 34°C and diel fluctuating temperatures of $22 \pm 2^\circ\text{C}$, $25 \pm 2^\circ\text{C}$, $28 \pm 2^\circ\text{C}$ and $31 \pm 2^\circ\text{C}$. The results showed that the growth rate of Chinese shrimp at the constant temperature regimes increased from 18°C to 31°C, whereas decreased significantly at 34°C. The growth rates of shrimp at $22 \pm 2^\circ\text{C}$, $25 \pm 2^\circ\text{C}$ and $28 \pm 2^\circ\text{C}$ were significantly greater than those at the corresponding constant temperatures of 22°C, 25°C and 28°C, respectively, whereas no significant difference was found between $31 \pm 2^\circ\text{C}$ and 31°C. As compared with those at constant temperature, the mean temperature at which maximum growth rate of shrimp occurred shifted to cooler temperature at diel fluctuating temperatures. The shrimp consumed more food at $25 \pm 2^\circ\text{C}$, $28 \pm 2^\circ\text{C}$ and $31 \pm 2^\circ\text{C}$ than those at 25°C, 28°C and 31°C, respectively, but no significant difference in apparent digestibility coefficient was found between the fluctuating and corresponding constant temperatures. The food conversion efficiency and energy assimilated into growth as percentage of energy from food for shrimp at $22 \pm 2^\circ\text{C}$, $25 \pm 2^\circ\text{C}$ and $28 \pm 2^\circ\text{C}$ were significantly higher than at the corresponding constant temperatures. Therefore, more food consumption, high food conversion efficiency and more energy partitioned into growth might contribute to the enhanced growth rate at the fluctuating temperatures.

KEY WORDS: constant temperatures, diel fluctuating temperatures, growth, energy budget, *Fenneropenaeus chinensis*, shrimp

INTRODUCTION

Temperature is one of the major physical factors influencing the growth rates of ectotherms. It is well known that the temperatures in natural aquatic systems fluctuate diurnally and seasonally. Most previous studies on the effects of temperatures on the growth of aquatic animals usually have been conducted under constant temperature regimes with an implicit assumption that growth in fluctuating temperatures would be approximated by growth at a constant temperature coinciding with the average temperature of the fluctuation. These studies have led to much insight into the influence of temperature on the growth of aquatic animals, however, the growth response of animals subjected to a fluctuating thermal environment, typical of those normally encountered in nature, would not have been examined (Hokanson et al. 1977, Cox & Coutant 1981). For example, the use of average temperature to characterize growth in fluctuating temperature regimes had been questioned by Hokanson et al. (1977).

Until now, many studies have been conducted to investigate the effects of fluctuating temperatures on a variety of aquatic ectotherms, such as zooplankton (Halbach 1973, Van As et al., 1980), bivalves (Widdows 1976, Pilditch & Grant 1999) and crustaceans (Dame & Vernberg 1978, Miao & Tu 1993, Miao & Tu 1996), and most of them focused on fishes (Biette & Geen 1980, Cox & Coutant 1981, Diana 1984, Konstantinov et al. 1989, Lyytikäinen & Jobling 1998, Lyytikäinen & Jobling 1999, Sierra et al. 1999, Zdanovich 1999, Baras et al. 2000). Because of the differences in species and thermal regimes, the results from different studies were very inconsistent.

Chinese shrimp *Fenneropenaeus chinensis* (Osbeck 1765) is the most important marine species cultured in China, comprising approximately 80% of the total shrimp production. Chinese shrimp are mainly distributed in the Yellow Sea and usually migrate for reproduction and overwintering twice a year in Bohai Sea, Yellow

Sea and East China Sea (Ge & Wang 1995, Miao & Tu 1995). Thus, not only Chinese shrimp have experienced temperatures diurnally and seasonally fluctuations, but also they normally are exposed to varying temperatures when they move in water masses, vertically and horizontally, during feeding, swimming or predator avoidance. Until now, although a lot of studies on the effects of temperatures on the growth of this species have been conducted, most of them have focused on the effects of constant temperatures (Zhang et al. 1983, Wang et al. 1984, Miao & Tu 1995, Zhang et al. 1998), and only a few work dealing with the effect of fluctuating temperature on the growth of shrimp (Miao & Tu 1996) was reported.

In a previous study, it was found that the oxygen consumption of Chinese shrimp at a fluctuating temperature of $27 \pm 3^\circ\text{C}$ was significantly lower than that at a constant temperature of 27°C (Tian et al. 2004b), whereas the growth rate of shrimp at $27 \pm 3^\circ\text{C}$ was significantly higher than at the corresponding constant temperature of 27°C (Tian 2001), which implicated that there could be a bioenergetic mechanism involved in this difference between fluctuating thermal regimen and corresponding constant temperature. Based on this assumption, this study was designed to evaluate the growth rate, food consumption (FC), food conversion efficiency and energy budget of Chinese shrimp at diel fluctuating temperatures and constant temperature. The physiological and bioenergetic mechanisms involved in the optimization of shrimp growth in fluctuating thermal regimes were also investigated.

MATERIALS AND METHODS

Experimental Shrimp and Acclimation

Chinese shrimp juveniles were obtained from the pond of the Hongdao Shrimp Farm, Qingdao, P.R. China. The shrimp were cultured in aerated fiberglass tanks with seawater and maintained at about 25°C for at least 3 days. Then the shrimp were acclimated to various constant temperature regimes, 18°C, 22°C, 25°C, 28°C, 31°C and 34°C at 1.5°C per day. When the desired tem-

*Corresponding author. E-mail: dongsl@mail.ouc.edu.cn

perature was reached, the shrimp were further kept in the target temperature for three days before the experiment started. During acclimation, the shrimp were fed twice daily to satiation with a commercial pellet manufactured by the Mawei Fishery Feed Co. Ltd., Fujian, China ($43.39 \pm 0.22\%$ crude protein, $9.74 \pm 0.30\%$ lipid, $9.91 \pm 0.05\%$ ash, $16.88 \pm 0.11\%$ energy and $8.41 \pm 0.06\%$ moisture). A 14 h light: 10 h dark photoperiod was maintained.

Experimental Design and Facility

The thermal treatments included 6 constant temperatures, 18°C, 22°C, 25°C, 28°C, 31°C and 34°C, and four diel temperature fluctuations with daily means between 22 and 31. There were four replicates for each thermal treatment. In the fluctuating temperature treatments, the pattern of diel temperature fluctuations imitated the daily natural rhythm of field water temperature at the site of the present experiment ($36^{\circ}1'N$, $120^{\circ}3'E$) and amplitude of temperature fluctuation was set at $\pm 2^{\circ}C$. The minimum temperature was set at 0600 h, and increased gradually to the maximum at 1400 h, then was decreased to the minimum again at 0600 h next day.

During the experiment, the ambient temperature was controlled at $16 \pm 0.5^{\circ}C$. Four glass aquaria ($45 \times 25 \times 30$ cm) were incubated in a water bath tank ($170 \times 75 \times 30$ cm) and the temperature of aquaria was controlled by water bath. Each aquarium was covered with a 5-mm screen to prevent the shrimp jumping out of the aquaria. Two recirculating pumps (35 W) were applied in each water bath tank to ensure the even distribution of water temperature in whole tank. Two systems were applied to control different water thermal regimes. The constant temperature was maintained by the thermostatic regulation of immersion heaters (WMZK-01). The actual temperature was daily calibrated with a mercury thermal meter to the nearest $0.1^{\circ}C$. In the treatment with fluctuating temperatures, each designated temperature range was controlled by a heating and cooling coil.

Experimental Procedure and Management

After thermal acclimation, 20 shrimp were randomly chosen, weighed individually and stocked into four aquaria for corresponding constant temperature treatment with each aquarium holding five individuals after 24-h feed deprivation. The same procedure was applied to choose shrimp from 22°C, 25°C, 28°C and 31°C thermal acclimation tanks and stock into aquaria for the diel temperature fluctuations treatments, i.e., $22 \pm 2^{\circ}C$, $25 \pm 2^{\circ}C$, $28 \pm 2^{\circ}C$ and $31 \pm 2^{\circ}C$, respectively. There were four aquaria for each thermal treatment. Ten shrimp were randomly sampled from each corresponding thermal acclimation tank for measurement of initial proximate body composition. During the experiment, the shrimp were fed twice daily to satiation (at 0600 and 1800 h) with commercial pellets. The uneaten feed and feces were separately collected using a siphon tube within 1.5 h after feeding. The collected uneaten feed and feces were settled in a beaker, and then the water above was removed carefully. The exuviae (molted exoskeletons) were collected at times. The uneaten feed, feces and exuviae were dried at $65^{\circ}C$, respectively, and kept for further analysis. FC was estimated from the difference between the amount of food applied into the aquarium and food uneaten. At the end of the experiment, all the test shrimp were collected after 24-h starvation and dried at $65^{\circ}C$ for 48 h.

The experiment was conducted from May 30, 2000 to July 2, 2000. During the experiment, water exchanges were made to all

treatments at the same time. Aeration was provided continuously and one-half to two-thirds of the water volume was exchanged every other day to ensure suitable water quality. Seawater used in the experiment was filtered by composite sand filter. During the course of the experiment, dissolved oxygen was maintained above 6.0 mg/L, the pH was around 7.8, ammonia was less than 0.24 mg/L, salinity of seawater was within 28–30 ppt, and a simulated natural photoperiod (14 L:10 D light/ darkness) was maintained.

Determination of Energy Contents and Estimation of Energy Budget

The energy contents of the whole shrimp, feed and feces were measured by the Parr 1281 Oxygen Bomb Calorimeter. The energy budget was calculated as the following equation for the crustacean energy budget (Petrusewicz & Macfadyen 1970):

$$C = G + F + U + E + R$$

where, C is the energy consumed in food; G , the energy deposited for growth; F , the energy lost in feces; U , the energy in excretion; E , the energy spent for exuvia, and R , the energy for respiration.

The estimation of U was based on the nitrogen budget equation (Levine & Sulkin 1979, Lemos & Phan 2001):

$$U = (C_N - G_N - F_N - E_N) \times 24,830$$

where C_N is the nitrogen consumed from food; F_N , the nitrogen lost in feces; G_N , the nitrogen deposited in shrimp body; E_N , the nitrogen lost in molting; 24,830, the constant of energy content in excreted nitrogen (J/g). The nitrogen contents in the formulated feed, shrimp, feces and molting shell were determined by the Kjeldahl method.

The value of R was calculated as the following energy budget equation:

$$R = C - G - F - U - E$$

Data Calculation and Statistical Analysis

All indices were calculated as follows: specific growth rate (SGR, %/d) = $100 \times (\ln W_t - \ln W_0) / t$; food conversion efficiency (FCE, %) = $100 \times (W_t - W_0) / C$; apparent digestibility coefficient (ADC, %) = $100 \times (C - F) / C$, where, W_t and W_0 are the final and initial weights (g), t is the feeding duration (d), C is daily FC (g), and F is the daily fecal production (g).

Experimental data expressed as aquarium means were analyzed using SPSS 10.0 (SPSS Inc., Richmond, CA, USA), with possible differences among data being tested by the student's t -test and one-way ANOVA. Duncan multiple range test was used to test the differences between treatments. $P < 0.05$ was accepted as the level of statistical significance. Log transformations were used to homogenize the variance of body weight before data analyses. Arc-sine transformations were used for feeding rate, FCE and apparent digestion rate to normalize the data distribution.

RESULTS

The growth rate of Chinese shrimp at constant temperatures increased with the temperatures from 18°C to 31°C, whereas it decreased significantly at 34°C (Table 1 and Fig. 1). Referred to studies of Miao and Tu (1993), the relationship between constant temperature ($T, ^{\circ}C$) and SGR of Chinese shrimp was best described by polynomial regression analysis:

$$\begin{aligned} \text{SGR} &= -0.0028T^3 + 0.1976T^2 - 4.3902T + 32.4816 \\ R^2 &= 0.8217 \quad F = 39.90 \quad n = 24 \end{aligned}$$

CT, constant temperature; FT, fluctuating temperature.

The shrimp exhibited different growth trends at diel fluctuating temperatures compared with those at constant temperature regimen (Table 1 and Fig. 1). The daily increment and SGR of shrimp at diel fluctuating temperatures changed from 13.94 mg per day and 2.54% per day to 29.70 mg per day and 4.11% per day, respectively. The growth rates of shrimp at 22 \pm 2°C, 25 \pm 2°C and 28 \pm 2°C were significantly greater than those at the corresponding constant temperatures of 22°C, 25°C and 28°C, respectively, whereas no significant difference was found between 31°C \pm 2°C and 31°C ($P < 0.05$). The best growth occurred at 28°C \pm 2°C under fluctuating temperature regimen, whereas best growth occurred at 31°C under constant temperature regimen. Thus, from the growth curves of shrimp, it can be seen that the mean temperature at which maximum growth rate of shrimp occurred shifted to cooler temperature at diel fluctuating temperatures as compared with those at constant temperature.

Compared with corresponding constant temperature, FC of shrimp at 25 \pm 2°C, 28 \pm 2°C and 31 \pm 2°C were significantly higher than at corresponding constant temperatures ($P < 0.05$); however, no significant difference was found between 22 \pm 2°C and 22°C ($P > 0.05$) (Fig. 2).

Figure 1. SGR of Chinese shrimp at constant and fluctuating temperatures. Each point is the mean \pm SE of determinations from four replicates, error bars represent 1 SE. NS means no significantly difference between the daily mean values of oxygen consumption of shrimp for the two patterns of fluctuating temperature regimen and control one and * means the significant difference ($P < 0.05$). CT, constant temperature; FT, fluctuating temperature.

There was no difference in ADC between diel fluctuating temperature and corresponding constant temperature ($P > 0.05$, Fig. 3).

Food conversion efficiencies of shrimp at fluctuating temperatures of 22 \pm 2°C, 25 \pm 2°C and 28 \pm 2°C were higher than at the corresponding constant temperatures of 22°C, 25°C and 28°C ($P < 0.05$), respectively, but there was no significant difference between 31°C and 31 \pm 2°C ($P > 0.05$) (Fig. 4).

Table 2 shows the patterns of energy allocation in the test shrimp at fluctuating temperatures and corresponding constant temperatures. The shrimp at the fluctuating temperatures of 22 \pm 2°C, 25 \pm 2°C and 28 \pm 2°C assimilated more energy for growth than those at constant temperatures of 22°C, 25°C and 28°C ($P < 0.05$), respectively, whereas no significant difference was found between 31 \pm 2°C and 31°C ($P > 0.05$). The shrimp at 28 \pm 2°C spent less energy in respiration than those at 28°C ($P < 0.05$). No differences were found between the fluctuating and corresponding constant temperatures in the allocation of consumed energy to feces, excretion and exuvia.

DISCUSSION

The positive influence of fluctuating temperatures on the growth of crustaceans has been reported in cladocerans, copepods, crabs and penaeid shrimp. The development and growth of *Daph-*

Figure 2. FC rate of Chinese shrimp at constant and fluctuating temperatures. For treatment abbreviations and symbols, refer to Fig. 2.

nia pulex (De Geer), *Pseudocalanus minutus* (Kroeyer), mud-crab *Rhithropanopeus harrissi* (Gould), Chinese mitten crab *Eriocheir sinensis* (H. Milne Edwards), redbtail shrimp *F. penicillatus* (Alcock) and Chinese shrimp increased at moderate diel fluctuating thermal regimes (Lock & McLaren 1970, Costlow & Bookhout 1971, Van As et al. 1980, Miao & Tu 1993, Miao & Tu 1996, Wang 1999). In this study, the shrimp at fluctuating temperatures of $22 \pm 2^\circ\text{C}$, $25 \pm 2^\circ\text{C}$ and $28 \pm 2^\circ\text{C}$ exhibited higher growth rate than those at corresponding constant temperatures of 22°C , 25°C and 28°C , and better growth occurred at $28^\circ\text{C} \pm 2^\circ\text{C}$. In comparison, the shrimp at 31°C grew best under constant temperature regimes. Thus, the mean temperature at which maximum growth rate of shrimp occurred shifted to cooler temperature at diel fluctuating temperatures as compared with those at constant temperature, which is similar to results of Hokanson et al. (1977) and Lyytikäinen and Jobling (1999) in rainbow trout *Salmo gairdneri* (Richardson) and Arctic charr *Salvelinus alpinus* (Linnaeus). The growth rate of shrimp appeared to be accelerated at fluctuating temperatures whose mean temperatures are below the corresponding constant optimum temperature for growth, whereas it retarded at fluctuating thermal regimes whose mean temperatures are above the constant optimum temperature for growth. This result indicated that the diel fluctuations within the range normally selected by shrimp (i.e., physiological optimum and lower) were beneficial to growth. Fluctuations at the mean temperatures above the physiological optimum, however, might inhibit the growth of shrimp.

Figure 4. FCE of Chinese shrimp at constant and fluctuating temperatures. For treatment abbreviations and symbols, refer to Fig. 2.

The mechanisms for the enhancement in growth of crustacean at diel fluctuating temperatures were still investigated less thoroughly. Dame and Vernberg (1978) showed that diel fluctuating temperature regimes significantly depressed oxygen consumption in the 15°C to 25°C temperature range in the mud crab *Panopeus herbstii* (H. Milne-Edwards) and the fiddler crab *Uca pugilator* (Bosc) when compared with rates of animals subjected to constant acclimation rates. Because this depression of metabolic rates occurs over that portion of the yearly temperature range within which the animals are most active, it is suggested that these organisms use energy more efficiently when subjected to natural cyclic temperature conditions than when subjected to constant temperature environments. Tian et al. (2004b) also obtained the similar result in Chinese shrimp. The oxygen consumption of Chinese shrimp at a fluctuating temperature of $27^\circ\text{C} \pm 3^\circ\text{C}$ was significantly lower than that at a constant temperature of 27°C , which could explain the increased growth at same fluctuating temperatures partially (Tian 2001). In this study, increased FC were found in shrimp at fluctuating temperatures of $25^\circ\text{C} \pm 2^\circ\text{C}$ and $28^\circ\text{C} \pm 2^\circ\text{C}$, and better FCE occurred at $22 \pm 2^\circ\text{C}$, $25 \pm 2^\circ\text{C}$ and $28 \pm 2^\circ\text{C}$, whereas there was no difference in ADC between diel fluctuating temperature and corresponding constant temperature. The study on energy allocation showed that the shrimp at fluctuating temperature of $22 \pm 2^\circ\text{C}$, $25 \pm 2^\circ\text{C}$ and $28 \pm 2^\circ\text{C}$ partitioned more energy for growth than those at constant temperatures of 22°C , 25°C and 28°C , respectively. Thus, the enhancement in the growth of shrimp in the present study could mainly be ascribed to energetic

advantage at optimal diel fluctuating temperatures, high FCE, reduced metabolism and more energy partitioned into growth although more FC might be one of mechanisms for increased growth as well.

DISTRIBUTION AND ABUNDANCE OF PELAGIC SHRIMPS FROM THE DEEP SCATTERING LAYER OF THE EASTERN ARABIAN SEA

P. K. KARUPPASAMY,¹* N. G. MENON,² K. K. C. NAIR¹ AND C. T. ACHUTHANKUTTY¹

¹National Institute of Oceanography, Regional Center, Kochi, India; ²Central Marine Fisheries Research Institute, Kochi, India

ABSTRACT The sonic scattering layer (SSL) or deep scattering layer (DSL) of the eastern Arabian Sea of India is found in depths between surfaces to 750 m with varying thicknesses and in multiple layers. There is a distinct resident community of pelagic shrimps that is widely distributed in the DSL biocomposition. Pelagic shrimps formed 19% of the total biomass and 47% of the micronekton biomass of the DSL. Many of them serve as important food resources to several pelagic/mesopelagic organisms. Pelagic shrimps concentrate in the deep scattering layer and diurnally migrate in the water column. The estimated average abundance pelagic shrimps ranged between 0.04–106 /1000m³. Shrimp catches were higher during night at 50–200 m depth than day. The dominant families encountered in the catches were Thalassocarididae, Pasiphaeidae, Sergestidae and Oplophoridae. Dominant genera of pelagic shrimps present were *Gemadus*, *Sergestes*, *Sergia*, *Lucifer*, *Oplophorus*, *Acanthephyra*, *Nematocarcinus*, *Leptochela*, and *Thalassocaris*. Species *Sergestes seminudus*, *Thalassocaris crinata* and *Leptochela robusta* were present in swarms.

KEY WORDS: pelagic shrimps, deep scattering layer, geographical distribution, vertical migration, swarming behavior

INTRODUCTION

Since the challenger expedition (1873–1876), the occurrence of bright red pelagic shrimps in the mid and deep waters of the ocean has been known. Recently, much attention has been paid to discover their role in the productivity of the ocean. The importance of pelagic shrimps as sonic scatters, food for larger animals, and as agents in energy transfer to the deep sea is well documented (Omori 1974, Kikuchi & Omori 1985). Marine organisms aggregate at specific depths in the ocean and the scattered sound waves from these organisms can be recorded as a scattering layer on the echogram of an echo sounder. This layer is referred to as sound-scattering layer (SSL) or deep scattering layer (DSL) and has been observed in all the oceans (Sameoto et al. 1985, Iida et al. 1996). Hays (2003) stated that the DSL organisms, which ascend around dusk and descend around dawn presumably reflecting the predator-prey tracking. Often discrete layers are evident at different depths, each layer composed of different species or developmental stages (Tarling et al. 2001). The DSL is a layer of living organisms, ranging from almost microscopic zooplanktons like copepods to macroorganisms like shrimps, squids and fishes that prey from within and outside the DSL (Ingmanson & William 1973). According to Omori (1974), out of a total of about 2,000 species of shrimps recorded from the world oceans, as many as 210 species pass their complete life in the pelagic realm. In Indian waters, the earliest studying on the taxonomy of pelagic shrimps was that of Alcock (1901) who listed several species along with benthic forms from the collection of the marine survey ship "Investigator." Later Kemp (1917, 1925), Nataraj (1942, 1947) and more recently Suseelan (1984) have recorded many more species from the west and east coasts of India and studied their taxonomy. Pelagic shrimp form important food and forage to oceanic tuna, flying fishes (James et al. 1987, Philip 1998) and a number of fish species inhabiting the shelf waters that support commercial fishery. Pelagic shrimp are considered potentially important from the outer shelf and slope waters of the west coast of India (Venkatraman 1960, Suseelan & Nair 1990). Therefore a detailed investigation

was carried out for understanding their distribution pattern, abundance and diel vertical migrations in the eastern Arabian Sea.

MATERIALS AND METHODS

The pelagic shrimp samples were collected from the DSL during the 10 cruises of FORV *Sagar Sampada* as part of a DSL program in Indian EEZ between May 1998 to December 2000 in the area between 06–21°N and 66–77°E (Table 1). Pelagic shrimp catches were recorded from 123 stations (88%) out of the 140 stations sampled, covering 67 night and 56 day samplings (Fig. 1). The gear used for the collection was the Isaac-Kidd Midwater Trawl (IKMT). The IKMT was designed to collect meso/bathypelagic specimens larger and more active than the specimens caught by plankton nets (Isaacs & Kidd 1951). The towing speed was maintained at 3 knots. Acoustic detection of DSL onboard was facilitated by two Echo sounders (Simrad, EK 400 and EK 200, 38 KHz/120 KHz). The IKMT was operated by observation of the DSL in the echogram, by making an oblique haul for 30 min. The sampling depth varied between 50 and 750 m and hauling depth depended on the concentration of DSL thickness as evidenced from echograms. The catches were preserved in 10% buffered formalin, after noting the volume, immediately after the haul. From the samples pelagic shrimps were sorted out and were used for the study. Identification of pelagic shrimps was done using the

key and description of species by Alcock (1901), Hansen (1919), Kemp (1920), Holthius (1955), Yaldwyn (1957), Kensley (1971 a, b), Judukins (1978), Burkenroad (1981), Suseelan (1984) and Farfante and Kensley (1997). The pelagic shrimp abundance was estimated using "Swept area" method (Sparre & Vanema 1992). The abundance per 1-degree square was calculated by taking into account the DSL thickness (m), the average numerical abundance of shrimps (No/1,000 m³) in the collections taken from that area and these have been extrapolated to compute the biomass for catch

1-degree square. Because the sample size was small for a realistic estimation of biomass, the estimation presented here is only an indication of the resource abundance in the surveyed area.

RESULTS

DSL Characteristics

The deep scattering layers are found throughout the surveyed area in the Arabian Sea. Single layers are found more frequently than multiple layers. The scattering layer is generally found in depths ranging between 200–750 m during day and surface to 200 m during night, with varying thicknesses and in multiple layers both day and night. The DSL multiple layers were recorded at

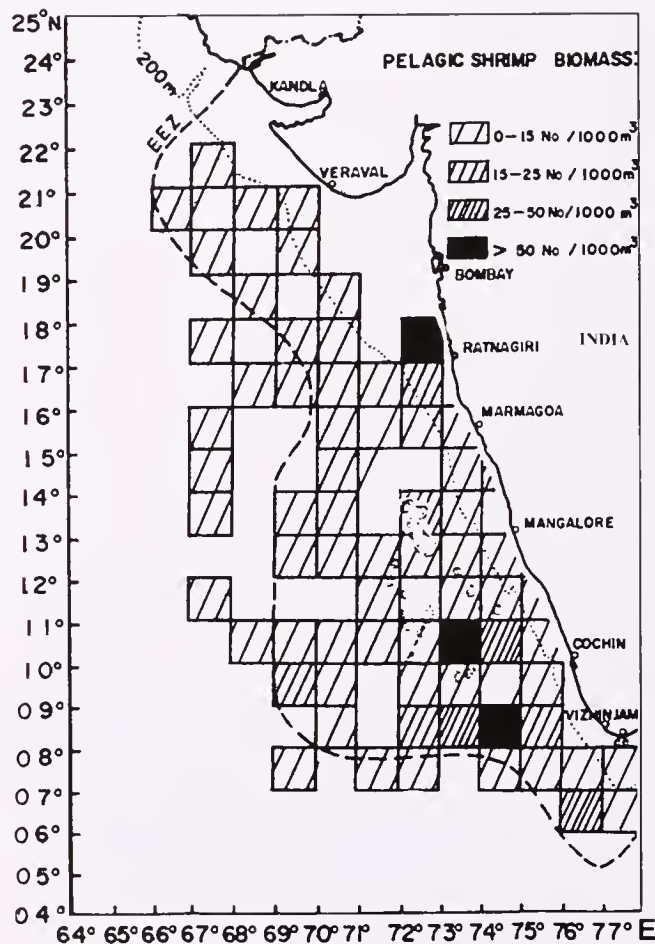

Figure 2. Geographical distribution and abundance (per/1,000 m³) of pelagic shrimps

Figure 3. Day and night numerical average abundance of different family of pelagic shrimps

three locations (Table 2) with varying thickness and characters. All three multiple layers were found in the southern regions of the Arabian Sea. The multiple layers invariably recorded in depths between 10–90 m, 20–250 m and 40–400 m. Collections made at different times of day and night indicated that discrete bands or layers ascend to surface from the upper DSL by dusk and during the day it descend down.

Geographical Distribution and Abundance of Pelagic Shrimps

There is a distinct resident community of pelagic shrimps found to be widely distributed in the DSL biocomposition. Of the total biomass, pelagic shrimps formed 19% of the total biomass and 47% of the micronekton biomass of the DSL. The result showed that the pelagic shrimps numerically formed one of the major components of the micronekton in the DSL (Table 3). Figure 2 shows the general distribution of the pelagic shrimps (average values for each 1° squares were plotted) in the Arabian Sea. The north (15–22°N)-south (06–15°N) comparison showed an increasing abundance of pelagic shrimps towards south (64.8% of the total catch). The numerical abundance ranged from 0.04–106/1,000 m³. Along the southwest coast the maximum biomass recorded was at 08–74° square (106/1,000 m³) off Vizhinjam and off Cochin (100/1,000 m³), whereas along the northwest coast high catches was recorded off Ratnagiri region (51/1,000 m³). The family-wise estimated average biomass for the whole study area is presented in Figure 3. During the night the families Thalassocaridae and Pasiphaeidae were more abundant (>20/1,000 m³) followed by families Sergestidae (3.94/1,000 m³) and Luciferidae (3.94/1,000 m³), whereas the families such as Oplophoridae, Benthesicymidae, Nematocarcinidae, Pandalidae, Penaeidae, Solenoceridae and Stenopodidae were recorded in small numbers. In the day catches all families were recorded (<2.5/1,000 m³) in small numbers. This showed that pelagic shrimps aggregate mostly during the night.

Vertical Migration

Changes in the abundance of pelagic shrimps in the IKMT catches could throw light on the nature of their vertical migration.

Figure 4. Day and night average abundance of pelagic shrimps (No./1,000 m³)

To study the variation in the vertical distribution of pelagic shrimps, the data arbitrarily were group into 4-depth realm namely, 0–50, 50–200, 200–300 and >300 m for convenience of explanation. The pelagic shrimps abundance was rich at depth-ranges 50–200 m (777/1000 m³) and 0–50 (554/1000 m³) and low catches were yielded from below 300 m. During the night, they were concentrated more in the upper strata (0–200 m) and during the daytime they were more abundant >200 depth (Fig. 4). Among the pelagic shrimps, the dominant groups considered for vertical dis-

	26	40	08°00'N	75°00'E	Day	September

tributional studies were Sergestidae, Pasiphaeidae, Thalassocaridae and Oplophoridae (Fig. 5). Night catches of pelagic shrimps belonging to all families from surface waters (0–200 m) exceeded the day catches. Catches from these depths were higher during the day than at night. Some groups migrate to the shallowest depths possible at night, whereas the deeper-water forms prefer to migrate only to mid depths. For example shrimp belonging to Oplophoridae family were not captured either during day or night from the 0–50 m depth range. They were caught from 200–300 m-depth range during both day and night.

Species Composition

The pelagic shrimps of the DSL were made up of 29 species belonging to 19 genera and 11 families. Shrimps belonging to genera *Oplophorus*, *Gennadas*, *Sergestes*, *Leptochela* and *Acanthephyra* were dominant in the DSL catches (Table 4). Out of the 29 species obtained, 16 were restricted to a few locations and 13 were represented along the entire eastern Arabian Sea. The survey results showed that the caridean shrimps, particularly *Acanthephyra sanguinea*, *Meningodora* sp., *Notostomus* sp., *Psathyocaris* sp., *Plesionika martia* and *P. alcocki*, were recorded only from the southern parts. The species *Funchalia dana*, *Solenocera hextii*, *Acetus japonicus*, and *Nematocarcinus tenuirostris* were only from the northern parts and all other species were distributed along the entire Arabian Sea.

Swarming Behavior

The swarming nature of pelagic shrimps was evident from the strong concentration on various occasions during this study. In the oceanic waters *Sergestes seminuds*, *Thalassocaris crinata* and *Leptochela robusta* occurred in swarms (Table 5). Swarming nature was noticed mostly in the lower latitudes, and only a few swarms were noticed in the northern region at 16°14'N, 72°15'E. In some of the hauls, shrimps formed more than 75% of the total catch. *Leptochela robusta* was found at 5 locations both during day and night, with maximum abundance at 10°29'N, 73°30'E in the depth of 50 and 90 m (256 & 99/1,000 m³) respectively. The *Thalassocaris crinata* was present only in the night collections at 3 locations, and the depth of occurrence ranged between 50–100 m and was caught during May and December with a maximum of 302/1,000 m³ at 08°33'N, 74°34'E. The species *Sergestes seminuds* was found at two locations during the day collections at depths between 40–430 m during April and September. The abundance was <30/1,000 m³ for these species.

DISCUSSION

The deep scattering layers are found in depth between surface and 750 m with the varying thicknesses and in multiple layers throughout the survey of the eastern Arabian Sea. Barham (1957) found that in Monterey Bay the number of layers changes throughout the year. Herring et al. (1998) recorded distinct multiple layers in the upper 350 m during the daytime off Oman coast. The striking feature noticed during this study was the presence of a high density of pelagic shrimps throughout the eastern Arabian Sea. The quantitative richness of the DSL in the Arabian Sea is mainly caused by the presence of micronektonic organisms like pelagic shrimps, swarming crabs, cephalopods and epi-mesopelagic fishes. Among the pelagic crustaceans occurring in the scattering layers of the sea, shrimps appear to occupy a prime position numerically (Suseelan & Nair 1990). Their distribution in fact shows a clear north-south variation as the abundance increased from north to south. The southern region was found to be more productive compared with the northern region of Arabian Sea, where their abundance was rather patchy and productive areas were less extensive. Overall biomass estimations showed that the maximum population densities were recorded off Vizhinjam (106/1,000 m³) and off Cochin (100/1,000 m³). Of the total 19% of the pelagic shrimps recorded from the DSL, species such as *Leptochela robusta*, *Sergestes seminuds* and *Thalassocaris crinata*, which are of high forage value, appeared in seasonal swarms during day/night. Their swarming is strongly seasonal and the fishing seasons correspond with the swarming periods. A study on the day-night variations in abundance revealed a pronounced vertical migration of these animals, being more concentrated in night samples than day. Herring et al. (1998) found that decapods (particularly species of *Gennadas*, *Plesionika* and *Sergestes*) contributed more to the biovolume among the micronekton of the DSL. Shrimps feed actively at night, however physiological evidence suggests that the lower meso and bathypelagic species are able to maintain their predatory activities throughout range of migration, by day as well as by night (Pearcy & Foress 1966). Waterman et al. (1939) stated that diurnal vertical migrations have long been known to play an important part in the lives of pelagic organisms. At night the animals were more densely packed in the depth ranges of 0–200 m, whereas, during the day these animals usually appeared at depths >200 m. Diel vertical migrations of pelagic shrimps are often extensive, hence accelerating the vertical flux of organic matter and recycling of chemical substances through the water column (Kikuchi & Omori 1985). Because fish such as tuna feed on pelagic shrimps, a positive

relationship between the abundance of these two groups could be expected (Alverson 1961). Among caridean shrimps recorded during the present study, a species that deserves special attention is *Leptochela robusta*, which was caught in large quantities throughout the west coast. This species is reported to form important forage to tuna and other pelagic fishes in the Lakshadweep and neighboring seas (George & Paulinose 1973, James et al. 1987). According to George et al. (1977) the maximum density of tuna and allied fishes in Indian EEZ is in the southwest coast and the oceanic islands. It is therefore reasonable to presume that the high productivity of pelagic shrimps might influence the abundance of tunas and allied fishes in these regions. The observation was made by James et al. (1987) that oceanic tunas that feed heavily on

Leptochela robusta is indicative of selective feeding of tunas on such species of pelagic shrimps. Voracious feeding on species of these genera by tuna (albacore) and fin and sei whales (*Balaenoptera borealis*) has been reported from the Pacific waters (Omori & Kawamura 1972, Omori 1974).

INDICATORS OF PERFORMANCE IN THE FISHERY FOR SHRIMP *PALAEMON SERRATUS* (PENNANT) IN IRISH COASTAL WATERS

EDWARD FAHY,* NIAMH FORREST, MARGARET O'TOOLE, RUTH MORTIMER AND JIM CARROLL

Fisheries Science Services, Marine Institute, Smughoro Road, Dublin 15, Ireland

ABSTRACT A commercial fishery for shrimp *Palaemon serratus* occurs on the south and west coasts of Ireland. Two temporal phases were identified: expansion from the mid 1970s to the late 1980s when maximum national landings were less than 150 t annually; and a second phase since 1990 when most years yielded more than 200 t. Maximum landings of 548 tons were reached in 1999. Three indicators of fishery performance are examined: total annual landings, weight landed per vessel per day and the average weights of individual shrimp in October and December, reconstructed from processors' records of graded shrimp. Total landings and daily landings weights correlated positively, whereas both correlated negatively with average individual shrimp weight in October and December over a 13-year period. Periodic and possibly cyclical recruitment events are identified as a contributor to improved yield.

KEY WORDS: *Palaemon serratus*, *Palaemon elegans*, Ireland, inshore, shrimp fishery

INTRODUCTION

A trap (creel) fishery for shrimp commenced in the vicinity of Baltimore, southwest Ireland in the mid 1970s (McPadden 1979). It subsequently expanded eastwards along the south and northwards along the west coasts. The species making up the majority of the landings was *Palaemon serratus* (Pennant), the smaller *P. elegans* accounting for less than 1% of landings by number (Fahy et al. 1998a). Cole (1958) and Forster (1951) described *P. serratus* as having a pronounced southern distribution in Britain and the majority of landings in Ireland came from the south west (Fahy & Gleeson 1996) (Fig. 1).

Shrimp are fished in plastic Chinese-hat-ended traps baited with whitefish or pelagic fish offal. Berried females fetch the best prices and are targeted by the fishery. These are most accessible and concentrated inshore during the autumn when growth is fast and an individual could double its weight in four to five months (Fahy & Gleeson 1996). However, shrimp are poorly selected by the square mesh used in creels (Fahy et al. 1998b); all sizes above 55 mm total length (which was the threshold at which recruitment commenced) are generally retained.

The growth and longevity of *P. serratus* have been investigated by a number of workers: Sollaud (1916) believed the species lived for five or six years; Cole (1958) thought it probable it survived for four but Forster (1951, 1959) favored two and Figueras (1986) described the expected life span as three years.

Significant elements in the life cycle reconstructed from data in Fahy and Gleeson (1996) and corroborated in Fahy et al. 1998b are presented in Figure 2 on which the traditional fishing season (August to January) is marked with rectangles whose shading indicates its relative importance to the industry (0-group shrimp are harvested and sold but they realize low prices, shrimp in their second autumn are the principal target and are most valuable, whereas female shrimp that might be in their third autumn are infrequent). Shrimp hatch in May and first recruit to the creels the following August and September. Discarding was an exceptional practice during the period under review (the majority of fishers sold the unsorted contents of their creels), hence 0-group animals were retained in the landings. Currently fishing also takes place up to 6

m offshore when the females migrate into deeper water during the colder months after the end of the year.

MATERIALS AND METHODS

Total landings of shrimp were collected by the government department responsible for fisheries (currently the Department of Communications, Marine and Natural Resources) on a national scale (Fig. 3).

Details of shrimp purchases and grading were obtained from five processors, labeled A to E. These processors purchased shrimp from a wide geographic range and several contemporaneously bought landings from the same area. Processors mechanically sorted shrimp using vibrating screens into four or five size grades at least five 1-kg samples of each of which were obtained and analyzed in the Marine Institute.

In the laboratory samples were disaggregated by sex; females have a faster growth rate than males. Individual measurements of total length from the tip of the rostrum to the end of the telson were noted (0.1 mm), the shrimp having been straightened against a rigid surface and individual weights (0.1 g) were recorded. Length frequencies separated by sex were predominantly bimodal with the two modes interpreted as the 0 and 1-y groups. However some females exceeding 24 mo in age may also have been present but not identifiable in the length frequencies. The bimodal length frequencies were sliced (separated at the lowest length frequency) to divide year classes. The consequence for the average shrimp weights of altering the proportions of the two age groups was modeled.

Definitions of grades varied from one buyer to another and the average weights of corresponding grades among processors differed; to maintain consistency of product, a processor maintained his sorting screen characteristics from one year to another. Table 1 contains the average weights of shrimp per grade analyzed by the Marine Institute and used throughout the period of the investigation to estimate the average individual weight of shrimp landed.

Processors provided details of the weight composition of graded shrimp in the landings they purchased (the actual weights of grades 1–4 or 5 after screening) together with dates and places of purchase, and from these and the average weight of shrimp within a grade the average weights of shrimp captured from an area in a specific time period was calculated according to the formula:

Figure 1. Map of Ireland on which the county boundaries are marked, showing the extent of inshore shrimp fisheries (black) and places where shrimp landings were recorded by the Department of Communications, Marine and Natural Resources (DCMNR) between 1995 and 2003 inclusive (x). Numbers 1–8 refer to the areas from which data on shrimp grading and daily landing weight per vessel were obtained. Places referred to in the text are identified.

$$\sum_{i=1}^n (GrWt_i * AvWt_i)$$

where $GrWt_i$ is the proportion of stock at this grade and $AvWt_i$ is its average individual weight, 1 was the largest and n the smallest grade.

The time period to which average weights referred was dependent on factory procedure: landings might be sorted daily or weekly and some archived data were for landings bought-in over a month.

The average individual weight in October and December was calculated using all consignments in these months. Grading was not always undertaken by a processor and such data as existed were not always made available. In 1991 grading details of 3% of total landings were obtained; the following year this increased to 98%. Thereafter it fluctuated between 20% (in 1993 and 2001) and 50% (in 1995), averaging at 35% over the period. In all 162 estimates of October and December weights were made and these were distributed among 92 combinations of processor, area and year from 1991 to 2003 (Table 2).

The majority of shrimp were fished mainly by small inshore vessels (<10 m) crewed by two persons fishing 300–500 creels. Logbooks were not maintained in this fishery. Records of daily landings by a single vessel, which were then consigned to a processor, were obtained from the same geographical range and from the same companies by scrutiny of payment records; individual boats were not identified. An estimated 3% of all landings were

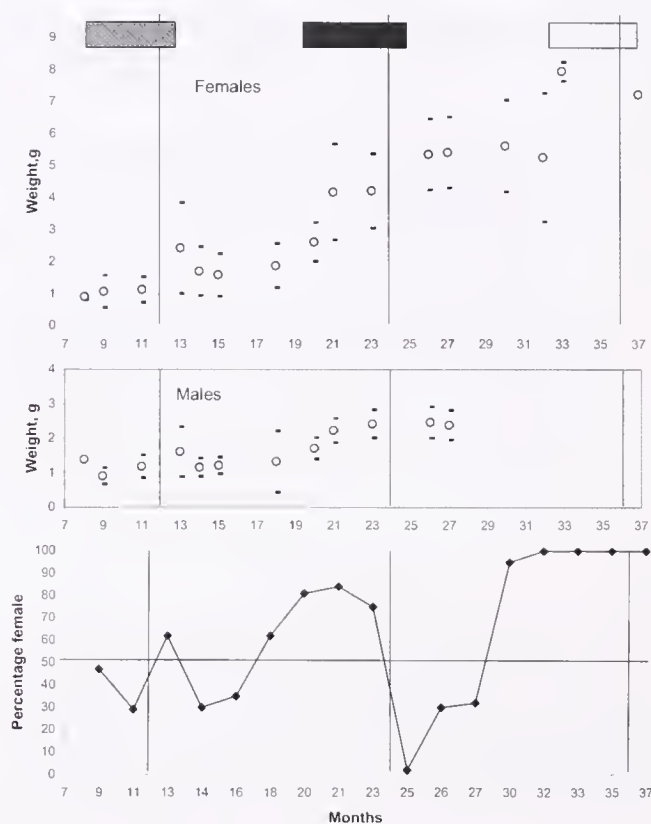

Figure 2. Elements of the shrimp life cycle of relevance to the inshore autumn commercial fishery whose duration (August to January) is represented by rectangle on the top panel. Relative importance of successive years is indicated by intensity of shading. Growth of females and males is shown as the mean ± 1 SD of the disaggregated and sliced length frequencies converted to weight. The last panel shows the sex ratio (from Fahy & Gleeson 1996 and Fahy et al. 1998h).

reported as daily landings in 1991 and 25% the following year. An average of 13% of total landings were reported as daily landings overall. Daily consignment numbers averaged 1,076 annually and ranged from 347 in 1991 to 1,906 in 1994.

The areas from which shrimp were purchased (numbered 1–8) are shown in Figure 1. Area 1 is in County Galway, area 2 is County Kerry, areas 3–7 are in County Cork, and area 8 is County Waterford.

The statistical package used in the work was SPSS 11.0.

RESULTS

The *Palaemon* shrimp fishery in Ireland is conducted close inshore in the autumn and it is concentrated on the south west of the country. Few shrimp are harvested in the Irish Sea (Fig. 1). A fishery exists in the northwest where shrimp accumulated in storage boxes are periodically collected for processing, which is also carried out mainly in the southwest. Between 1995 and 2003 the counties that provided the data on which this investigation is based recorded 93% of the total landings of shrimp (Galway, 20%, Kerry, 23%, Cork 45% and Waterford, 6%).

The fishery targeted 1-group shrimp (Fig. 2), especially females, which are twice as heavy as males during their second autumn. The fishery was mainly conducted from August to January when 1-group females moved close inshore. Females outnumber males in landings, the majority of which are harvested within 1 n m of the coast. Not all females have reached their asymptotic length at this age however and they continue their growth in deeper water during the colder months. Very few females survive to contribute to the next fishing season. Investigations on shrimp in southwest Ireland in the mid1990s supported Forster's interpretation of life expectancy for practical assessment purposes although the longevity of some few females might exceed 24 mo (Fahy & Gleeson 1996).

Annual landings (Fig. 3) had 2 phases: a period of low catches up to 1989 (142 t in 1982 was exceptional) and a subsequent period of expanded catches; other than in 1992 when they totaled 164 and in 1993 269 t, landings of shrimp exceeded 300 t per year during the latter period. In 1999 landings peaked at 548 t after which they fell to 115 t in 2002, recovering again to 413 t in 2004.

Mean daily landings per boat over the period were 34 kg (ranging from 23 kg in 1992 to 45 kg in 1998) and analysis of weight frequency over the period recorded 90% was less than 75 kg ($n =$

12,669, between 1990 and 2003). Landings of as low as 2 kg were recorded and the upper end of the range was at 250 kg (Fig. 3). Daily average consignment weights correlated significantly with total landings ($r^2 = 0.353$, $n = 14$, $P = 0.0251$).

All processor/area/year combinations of data covering the period September to December were considered in this analysis and for these the average individual shrimp weights in October and December were calculated. Selections of these data sets are shown in Figure 4 to illustrate the nature of the data. In the majority of panels there was some increase in weight in the autumn months and the average individual weight frequently declined coinciding with the move of females into deeper water in the colder months.

Forster (1951), Cole (1958), Sollaud (1916) and Desbrosses (1951) identified a number of variations in growth and biology of Palaemonid shrimp, which might be attributed to location (sex ratio favors females in rocky areas and males where the substratum provides less cover, for example) so the average individual weights were examined for bias, which might be linked to processor or area. Average individual weights were higher in areas 1 (4.95 g) and 8 (4.92 g) than elsewhere (3.9–4.2 g). In the rocky environment of Connemara (area 1) shrimp are known to be of better commercial quality because of the higher incidence of berried females. All records from area 1 were provided by processor D. Two processors, A and B, handled shrimp from area 8 and both provided a similar weight range. Area 8 includes the only area in which fishers were known to have graded their catches. An analysis of variance found a significant difference between processor and average shrimp weight ($df = 3$, $F = 3.420$, $P = 0.019$) and between area and average shrimp weight ($df = 6$, $F = 2.740$, $P = 0.015$) but average shrimp weights in samples from the same area handled by different processors did not differ significantly ($df = 4$, $F = 1.685$, $P = 0.157$).

Areas 1 and 8 had higher average shrimp weights, but data from these areas were more plentiful in some years than others hence, when they did occur they might have distorted the results in those years, so samples from areas 1 and 8 were excluded from all further analyses, and 147 average individual shrimp weights were used in the remaining calculations.

Average individual shrimp weights displayed periodic trends during the study period: between 1991 and 1995 average individual weights in October and December rose ($x\text{-var} = 0.365$; $n = 29$, $r^2 = 0.0384$, $P = 0.0003$), from 1995 to 1998 they declined ($x\text{-var} = -0.189$, $n = 30$, $r^2 = 0.152$, $P = 0.033$) and from 1998 until 2001 they increased again ($x\text{-var} = 0.315$, $n = 52$, $r^2 = 0.270$, $P < 0.0001$) (Fig. 5). A trough occurred in 1998 and the average weights tended downward again, though not significantly, between 2001 and 2003.

Average individual shrimp weight correlated negatively with daily consignment weight ($n = 147$, $r^2 = 0.0816$, $P = 0.0005$) and national landings ($n = 147$, $r^2 = 0.0711$, $P = 0.001$).

A correlation of average shrimp weight with time, superimposed on the data in Figure 6, suggests an increase in average shrimp weight over the period of the study.

The relationship between the proportion 0-group and average individual shrimp weight was modeled on the composition of shrimp samples provided in October and November by processor A. Disaggregated into males and females the length frequency compositions were sliced into 0 and 1-groups. In the model the proportion of 0-y shrimp was increased and the consequent aver-

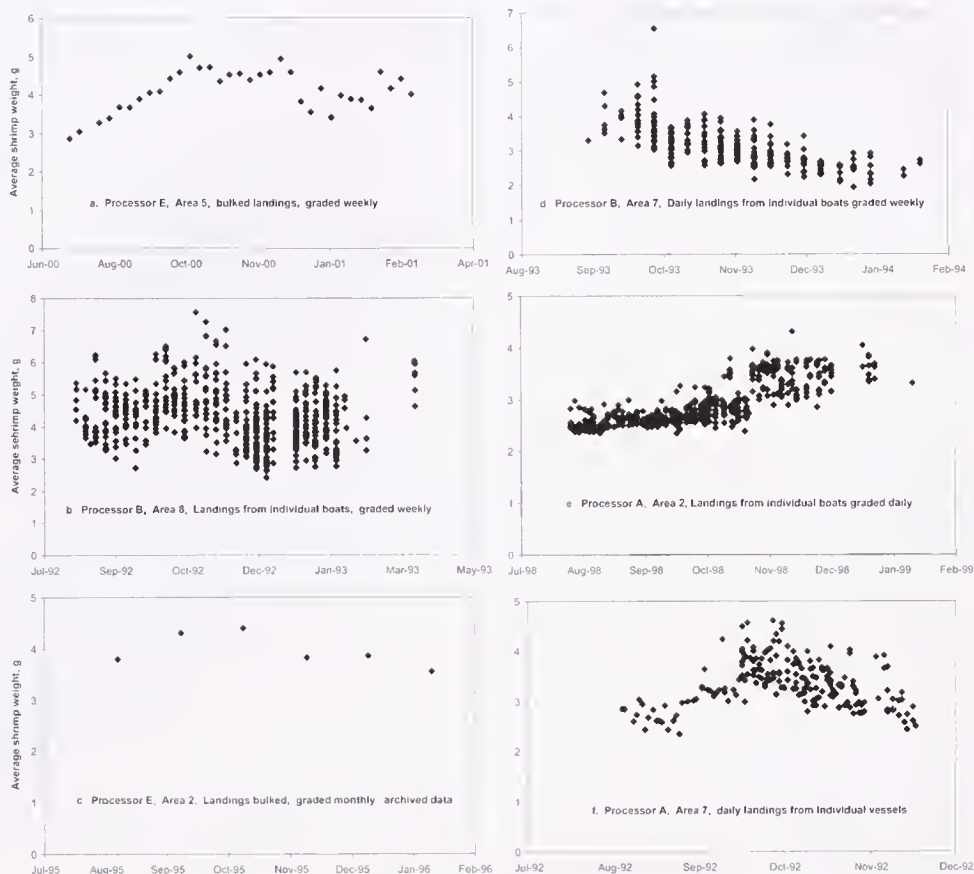

Figure 4. Examples of the seasonal distribution of average shrimp weights in landings from four areas in five years. On each the area and processor are identified. The examples are selected to illustrate the type of data used in the calculations: panel a, is of bulked daily landings, which were graded on a weekly basis, b and d are individual daily landings, which were graded on a weekly basis, e and f are daily landings, which were graded on a daily basis and c is graded material archived on a monthly basis.

age individual shrimp weight was noted (Fig. 7). An inverse relationship between average shrimp weight and the proportion of 0-group shrimp also suggested that the recruitment of 0-group shrimp influenced yield.

Figure 5. Range and mean values of average shrimp weights in October and December as reported by five processors (above) from eight areas (below).

DISCUSSION

Expanding from the mid 1970s, the inshore fishery for shrimp reached its maximum geographical extent in the early 1990s. The fishery is unregulated.

The maximum average individual weight in a shrimp catch from the inshore fishery is recorded in the late autumn, between October and December. Average individual weight is influenced by the sex ratio within the catch, whether it has been sorted to remove 0-group individuals and the relative proportions of 0 and 1-group animals represented (Fahy & Gleeson 1996, Fahy et al. 1998b).

Annual shrimp landings correlated positively with daily landings suggesting that the latter reflected changes in shrimp abundance. Greater abundance of a target species attracts additional fishing effort and that, in turn, increases yield. While logbooks were not maintained in this fishery, it is possible to obtain an estimate of fishing effort from the average daily and total annual landings. Using these data fishing days annually would have averaged 9,266 between 1991 and 2003 and ranged from 3,263 in 2002 to 13,650 in 1994. Fishing effort is strongly correlated with total landings ($n = 13$, $r^2 = 0.6919$, $P = 0.0004$).

Successful fishing could be based on a strong 1-y class of higher first sale value or an abundant 0-y class contributing greater volume but less unit value. In the analysis annual landings and daily consignment size both correlated negatively with average shrimp weight in October and December suggesting that increased

Figure 6. Trends in the average weights of shrimp in October and December, 1991 to 2003. Short-term sequential regressions and the long-term linear trends are shown and the variables for the latter are given.

landings were caused by greater proportions of 0-group shrimp and increased recruitment.

Figure 7 illustrates how a decreasing average shrimp weight signals this recruitment but is not a sensitive indicator. Modeled average shrimp weights were 5.45 g when they consisted of only 1-group animals; demonstrable change was brought about by the addition of an equal weight of 0-group shrimp, which reduced the average weight to approximately half (2.85 g). Doubling the addition of 0-group shrimp further reduced the average weight to 2.42 g (by a further 0.44 g) and tripling it reduced the average weight to 2.27 (by an additional 0.15 g). In terms of numbers, working from the data shown in Figure 2, the addition of 6:1 0-group to 1-group could increase the total weight of a consignment in the autumn fishery by 300%.

An investigation of the commercial shrimp fishery (Fahy & Gleeson 1996) provided some analyses of the age and sex composition of graded shrimp but had limited access to quantitative factory grading data. Without disaggregating for sex, they sliced the length frequency distributions at three points (65, 70 and 75 mm) to separate the 0 and 1-groups. At the time (early 1990s) there would have been a low incidence of 0-group shrimp in the landings anyway, but the slice point was also too far to the left, 85 mm would have been more appropriate. Fahy and Gleeson's review of the fishery in the 1990s considered it well managed. However, they noted the tendency for the autumn fishery to extend over a longer period, a trend that has since accentuated. The pursuit of shrimp offshore during the colder months of the year has also intensified as stock depletion of other inshore species and the capitalization of the inshore sector have progressed.

Fahy and Gleeson (1996) reported that shrimp are berried for much of the year: 1-group females become ovigerous in the autumn but 0-group come into berry the following spring. Berried

Figure 7. Modeled inverse relationship between average shrimp weight and the proportion of 0-group shrimp in the landings.

females are the most commercially valuable category of shrimp and confining the fishery to the autumn allowed the surviving 0-group cohort to reproduce. They expressed concern that a fishery extending over much of the year could deplete shrimp spawning stock biomass.

The gradual upward trend in average weights since the fishery completed its full expansion in the early 1990s (Fig. 6) may indicate a trend towards lower recruitments. Episodic larger recruitments are associated with shrimp of small average size and low value; larger shrimp are more valuable and their exploitation offshore when stocks are at a low level combined with their exploitation during the spring reproductive phase could culminate in growth overfishing, and this may now be a reality. A precautionary approach to prevent growth overfishing is required and an obvious initiative would be the restoration of the traditional fishery confining exploitation to inshore waters in the autumn months.

ACKNOWLEDGMENTS

The following processors provided data and samples for these investigations: Carr & Sons, Tallow, Co Waterford, Glenmar Shellfish, Skibbereen, Co Cork, Eiranova, Castletownbere, Co Cork, Bereci Shellfish, Middleton, Co Cork and Porcupine Fisheries, Cleggan, Co Galway. Eadaoin Healy of RPS consultants, Letterkenny, mapped inshore shrimp fisheries presented in Fig 1. Trevor Alcorn, of the Marine Institute, provided advice on GPS and Jonathan White and Neil O'Maoileidigh commented on an earlier draft of the MS.

DISTRIBUTION OF THE SEA URCHIN *HEMICENTROTUS PULCHERRIMUS* ALONG A SHALLOW BATHYMETRIC GRADIENT IN ONAGAWA BAY IN NORTHERN HONSHU, JAPAN

YUKIO AGATSUMA,¹* HIROKAZU YAMADA² AND KAZUYA TANIGUCHI¹

¹Laboratory of Marine Plant Ecology, Graduate School of Agricultural Science, Tohoku University, Aoba, Sendai, Miyagi 981-8555, Japan; ²Shizuoka Prefectural Fisheries Experimental Station, Izu Branch, Shirahama, Shimoda 415-0012, Japan

ABSTRACT Distribution of the sea urchin *Hemicentrotus pulcherrimus* was monitored monthly or bimonthly from April 1998 to May 1999 at a 100 m² permanent site in intertidal to subtidal zones at depths of up to 2.8 m in Onagawa Bay, northern Honshu, Japan. Factors causing seasonal demographic changes were analyzed from vertical algal vegetation, sea urchin size, gonad development, and gut content. The highest density of *H. pulcherrimus* was found on algal turf on boulders at the depth of 0–0.3 m. Migration of adult sea urchins on crustose corallines at the depth of 0.3–2.8 m to the algal turf and subsequent inhabitation in more suitable boulder habitat are suggested from November to March, when *Acrosorium polyneurum*, which is their main food, grew dominantly. As the high gut content of crustose coralline of the sea urchins on crustose corallines resulted in significantly lower gonad indices, it is likely that migration is caused by their high foraging activity for *A. polyneurum* to ensure gonad development. The growth of the sea urchins on algal turf was ensured by *Chondrus* spp. as main food.

KEY WORDS: sea urchin, *Hemicentrotus pulcherrimus*, distribution, gonad development, gut content, migration, *Acrosorium polyneurum*.

INTRODUCTION

The sea urchin *Hemicentrotus pulcherrimus* (A. Agassiz 1863) is found in intertidal and subtidal zones from Kyushu to Rebun Island, Hokkaido, Japan and in Korea and China (Shigei 1995, Agatsuma 2001a). This sea urchin is an important fisheries resource in shallow waters in the coastal regions of the southern Japan Sea from Fukui Prefecture. The brands “Echizen Uni” in Fukui Prefecture and “Shimonoseki Uni” in Yamaguchi Prefecture are well known. In Fukui, stones were introduced in 1910 to enhance the sea urchin’s habitat (Andrew et al. 2002, Agatsuma et al. 2003). Adult sea urchins with poor gonad development have been transplanted to kelp forests, where gonad development improves (Andrew et al. 2002, Agatsuma et al. 2003). In addition, seed production was initiated in a Yamaguchi hatchery in the 1960s (Sakai et al. 2003). The seeds (juveniles) of *H. pulcherrimus* were released in Saga, Shimane and Fukui Prefectures, and the number exceeded 1000,000 individuals in 1993, releases ranged from 390,000–890,000 individuals until 2000 (Agatsuma et al., 2003).

Quantifying seasonal patterns in density and size distributions among different habitats is necessary for managing and sustaining populations of sea urchins. In addition, the seasonal habitat selection relative to age and associated with algal assemblage as food resources that ensure growth and gonad development should also be clarified. In shallow waters in the Sea of Japan, Hokkaido, 0-y-old *Strongylocentrotus nudus* inhabit crustose coralline communities where the larvae settle (Taniguchi et al. 1994, Sano et al. 1998) throughout the year. Sea urchins that are >1 y old migrate to the kelp *Laminaria religiosa* bed in an intertidal zone, where their gonads are ensured to develop for reproduction from summer to autumn. They then return to the crustose corallines to avoid the strong wave action in winter (Agatsuma 2001b). A similar seasonal migration of *S. nudus* is also found in Pacific coastal waters, where an *Eisenia bicyclis* forest grows in subtidal shallow waters (Sano et al. 1998, Sano et al. 2001). Adult *Paracentrotus lividus* migrate from a pebble area where larvae settle to a *Cymodocea*

nodosa sea grass bed in relation to a change in food habit (Fernandez et al. 2001). The migration of *Sphaerechinus granularis* from *Phymatolithon* communities to *Zostera marina* or macroalgal beds is also related to changes in food habit (Guillou & Michel 1993). *Loxechinus albus* with >45 mm diameter also migrate from the intertidal zone where larvae settle to brown macroalgal beds at a depth of 4–15 m (Contreras & Castilla 1987). However, except for *S. nudus*, the principal purpose for migration is not clear. And that, there is no known reason for sea urchins to migrate, and the foods that they forage have not been identified by analysis of their gut content. In the life history of *H. pulcherrimus*, seasonal changes in the vertical distributions and the algal foods in relation to algal vegetation are also unknown.

In the present study, we monitored the density and test diameter of a *H. pulcherrimus* population in relation to the depth, bottom characteristics, and vertical algal vegetation from intertidal and subtidal zones in the Pacific near shore waters of northeastern Honshu. An analysis of the gut content was undertaken to determine the foods for gonad development and growth. Consequently, the factors contributing to seasonal demographic changes were suggested.

MATERIALS AND METHODS

Site Characteristics

A monthly or bimonthly survey was conducted in the intertidal and subtidal zones at Sashigahama (38°28'N, 141°29'E) in Onagawa Bay, Miyagi, from April 1998 to May 1999 (Fig. 1). Previously, a study site was determined from predominance of *H. pulcherrimus* by SCUBA diving observation. A survey was performed using one fixed transect (50 m long × 2 m wide) as the study site placed perpendicularly to the coast line.

In April 1998, the bottom profile at the study site was sketched precisely using a 1 × 1 m quadrat by SCUBA. Depth was measured with a water-pressure gauge (Japan Aqualung Co., Ltd.) at an interval of 1 m along the leaded rope placed at the center of the study site, and compensated at the level of the shallowest water. Algal vegetation at the study site in each quadrat was observed

Figure 1. Location of the study site in Onagawa Bay in northern Honshu, Japan.

using SCUBA and video-recorded (Handycam, DCR-TRV7, Sony Corporation). Unidentified algae in the field were collected and identified in the laboratory.

The mean surface water temperature every ten days during the present study and the averages for 30 y from 1968–1997 were referred to the data at Enoshima (38°24'N, 141°36'E) near the study site, measured by Miyagi Prefecture Fisheries Research and Development Center.

Density and Size Analysis

In the study site, a 1 × 1 m quadrat was used, and the test diameter of *H. pulcherrimus* was measured in each quadrat with a vernier caliper (1 mm accuracy); the results were recorded on aqua-notes by SCUBA. The sea urchins were replaced in the same quadrates. No survey was performed at a distance of 0–25 m in January 1999 because of the high wave action.

Strongylocentrotus nudus and *S. intermedius* also distributed in the study site and their density in each quadrat was also recorded. Throughout the year, *S. nudus* was found on deep crustose corallines with density of 4.5–8.4 individuals/m². Low density of <2.5 individuals/m² was found for *S. intermedius*.

Gonad Analysis

To determine the gonad development and feeding habits during the study, except for April 1998, a 50 m leaded rope was set up at a distance of 15 m west of the site, where similar algal vegetation was observed. Twenty specimens of *H. pulcherrimus* larger than 3 cm in diameter, which exceeds the mature size (Kawana 1938), were collected from algal turf along the line. Similarly, 5–10 specimens were collected at crustose corallines. The test diameter and body weight (g wet weight) were measured using a vernier caliper

(0.1 mm accuracy) and an electronic balance (0.01 g accuracy). Gonad wet weight was also measured (0.01 g accuracy), and gonad index (gonad weight × 100/body weight) was calculated. Part of the gonad was preserved in 20% formalin for 24 h, and after that, in 10% formalin. Using standard histological techniques, serial cross sections (6 µm) were cut through the center of a gonad and stained with Mayer's hematoxylin and eosin. Histological sections were classified according to Fuji (1960): Stage I, recovering; Stage II, growing; Stage III, premature; Stage IV, mature; and Stage V, spent.

Gut Content Analysis

Five specimens with a test diameter in excess of 3 cm were used to analyze the gut content on algal turf and crustose corallines. The gut content for each individual was obtained and filtered on a nylon net with a mesh size of 350 µm. The component of fractions <350 µm was excluded because it was difficult to sort. First, the components were divided into three groups, algae, animals and minerals, according to shape, color, and hardness with the use of a stereomicroscope. Furthermore, algae were classified into a family, genus, or species from its specific cell structure using a dissecting microscope. After that, each food item sorted was sucked on filter paper (Whatman GF/C) and dried for 12 h at 80°C in a hot-air convection oven and then weighed using a microbalance (1 mg accuracy).

Statistical Analysis

Statistical difference in densities of *H. pulcherrimus* at each four of the characterized areas in the study site among months and the densities among four areas was analyzed by two-way repeated ANOVA and Scheffé's multiple comparison test. Significant difference in the gonad indices on algal turf and crustose corallines among months was analyzed by one-way factorial ANOVA and Scheffé's multiple comparison test. The difference in indices between the two vegetation types were analyzed by unpaired *t*-test after confirming no significant difference in variance between them by *F*-test. All the data showed normal distribution and homogeneous variance by Shapiro-Wilk's *W*-test and Cochran's test, respectively.

RESULTS

Site Characteristics and Seawater Temperature

At the study site, boulders formed >50% of the substrata at the study site at distances of 10–17, 25–34, and 42–50 m. In the other areas, undulating rocks with ditches and holes in addition to boulders were present (Fig. 2).

The depth and seasonal changes in the vegetation of the dominant algae with these coverage of ca. >50% in the study site are shown in Figure 3. The area at a distance of 0–10 m is in the intertidal zone. Subsequently, the area sloped gently from 10–24 m at depths of up to 0.3 m and steeply from 24–50 m at depths of 0.3–2.8 m. From the upper to the lower intertidal zone, *Gloiopeltis furcata*, *Analphus japonicus*, and *Sargassum fusiformis* grew all year round. *Sargassum thunbergii* generally grew below *S. fusiformis*, except for the period from September to December, when *Chondria crassicaulis* grew dominantly. From the lower intertidal zone to the subtidal gentle slope at depths of up to 0.3 m, *Chondria ocellatus* and *C. verrucosus* grew dominantly from April to December. However, their growth zone was reduced to the lower

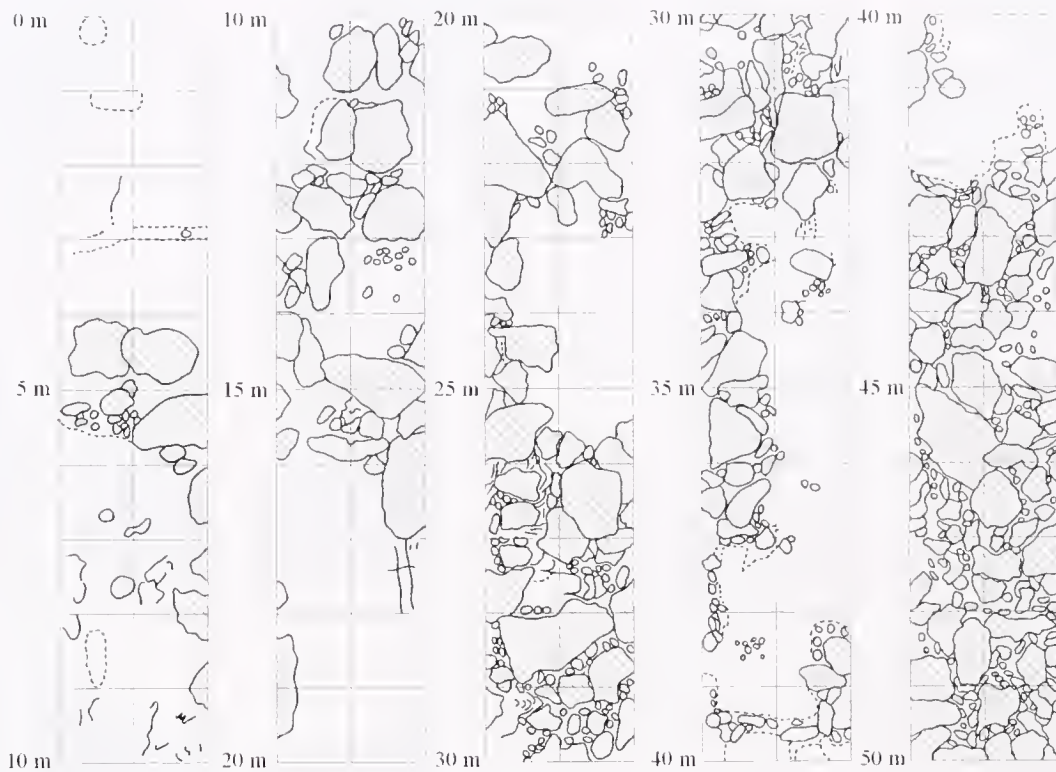

Figure 2. Bottom profile at the study site sketched using a 1 × 1 m quadrat. Dashed lines represent rocks with ditches or holes.

intertidal zone in March and May the following year. From September to December, *Grateloupia livida* and *Acrosorium polyneurum* colonized the *Chondrus* growth zone. In March and May, *A. polyneurum* grew dominantly at a depth of 0–0.2 m. *Sargassum yezoense* and *S. micracanthum* grew on rocks at a depth of 0.3 m all year round. Those sargasso algae grew abundantly in June and July. After dieback, the holdfasts and stipes remained from September to March. At the deeper zone of >0.3 m, crustose corallines dominated, whereas *Dilophus okamurae* grew at a depth of 2.1–2.8 m from September to March and dominantly from October to January. The study site was characterized by depth, algal vegetation, and bottom character; the intertidal zone, the algal turf with gentle slope at the depth of 0–0.3 m, the upper steep-sloped crustose corallines at the depth of 0.3–1.0 m, and the lower steep-sloped crustose corallines at the depth of 1.0–2.8 m.

Except for the period from February to April and August, the water temperature during this study was markedly higher than the average. In particular, the deviation showed high values of 3.8°C in late December 1998 and 2.0–2.4°C in January and late April 1999 (Fig. 4).

Vertical Distribution

Seasonal changes in the density of *H. pulcherrimus* on the 4 characterized areas in the study are shown in Figure 5. Significant difference in the density among 4 areas ($df = 3$, $MS = 3951.505$, $F = 163.587$, $P < 0.0001$) and month ($df = 9$, $MS = 9.898$, $F = 4.529$, $P < 0.0001$) was found. Significant correlation between the area and month was also found ($df = 27$, $MS = 75.719$, $F = 6.872$, $P < 0.0001$). The densities on algal turf were significantly higher than those on the other areas throughout the year ($P < 0.01$). There, the sea urchins were found beneath the boulders. Subse-

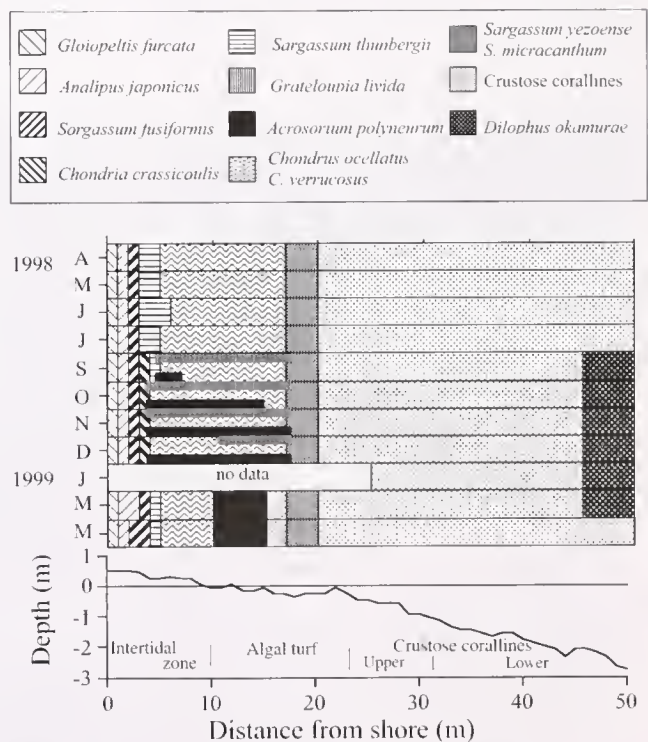

Figure 3. Depth and seasonal changes in the vegetation of the dominant algae with these coverage of ca. >50% at the study site characterized by the four areas, intertidal zone, algal turf, upper crustose corallines and lower crustose corallines.

Figure 4. Surface water temperature during the study at Enoshima, near the study site during this study (solid line) and for 30 y average (dotted line) from 1968 to 1997.

quently, their densities on upper crustose corallines were significantly higher than those on intertidal and lower crustose corallines, with the exception of September 1998 and March and May 1999 ($P < 0.01$).

The densities on the intertidal zone were low all year round. On algal turf, the densities from April to December 1998 ranged from 14.4–17.9 individuals/m², and no significant difference was found ($P > 0.05$). Then, the density significantly rose to 28.3 individuals/m² in March ($P < 0.05$). In May, it was also higher than from April to November the previous year ($P < 0.05$).

On the upper crustose corallines, the densities from November 1998 to January 1999 were significantly higher than those from May to September 1998 ($P < 0.05$). In addition, those in December and January were higher than that in October ($P < 0.01$). In particular, in January, the density reached a peak of 11.6 individuals/m². Whereas, it significantly fell in March and May 1999, when it reached a peak on algal turf ($P < 0.01$).

On the lower crustose corallines, the densities were low all year round. In January, the density reached a peak of 3.3 individuals/m², significantly higher than that each month the previous year, with the exception of November ($P < 0.01$). The density in November was higher than those in May, June, and September 1998 ($P < 0.05$). The density in March and May 1999 was significantly lower than that in January ($P < 0.01$), as observed on the upper crustose corallines. Thus a marked increase in the density of urchins on the algal turf from November to March was found.

The density on the algal turf in March 1999 was significantly higher than that in April 1998 ($P < 0.01$), whereas that on the upper crustose corallines showed a significantly low value ($P < 0.05$).

Size Frequency Distribution

Changes in the test diameter frequency distribution of *H. pulcherrimus* in each of the 4 areas are shown in Figure 6. At each area, sea urchins of 30–39 mm test diameter were predominant. On algal turf, the mode of test diameter distribution clearly shifted from 36–38 mm to 40–42 mm from June to December 1998. On the other hand, the sea urchins with 32–36 mm in test diameter increased and the mode shifted to 34–38 mm in March and May 1999, when the sea urchin densities rose significantly. On the

Figure 5. Seasonal changes in the density of *Hemicentrotus pulcherrimus* at the four areas, intertidal zone, algal turf, upper crustose corallines, and lower crustose corallines, at the study site. Vertical bars represent standard deviations. N.D. represents no data.

upper crustose corallines, the mode was around 40 mm from June to October, whereas urchins of 30–38 mm test diameter increased from November to January. Moreover, sea urchins of 32–36 mm test diameter were clearly found in each area in April and May 1998.

Gonad Development Process

The gonad development of the sea urchins was classified into five stages from histological observation as shown in Figure 7, and the seasonal changes on algal turf and crustose corallines were shown in Figure 8. From June to September, the gonads of the sea urchins at each algal community were in the recovering stage, with small numbers of oocytes and spermatocytes, with nutritive phagocytes filling the lumen (Fig. 7, 1A, 1B). Then, they progressed from the growing stage (Fig. 7, 2A, 2B), with increasing numbers of oocytes or spermatocytes along the acinar wall in October, to the mature stage (Fig. 7, 4A, 4B), in which most of the lumen is filled with ova and spermatozoa, in December or January. For long periods from January to June, the spent stage continued, with some relict ova and spermatozoa and empty spaces in the lumen (Fig. 7, 5A, 5B).

Seasonal changes in the gonad indices of the sea urchins at each

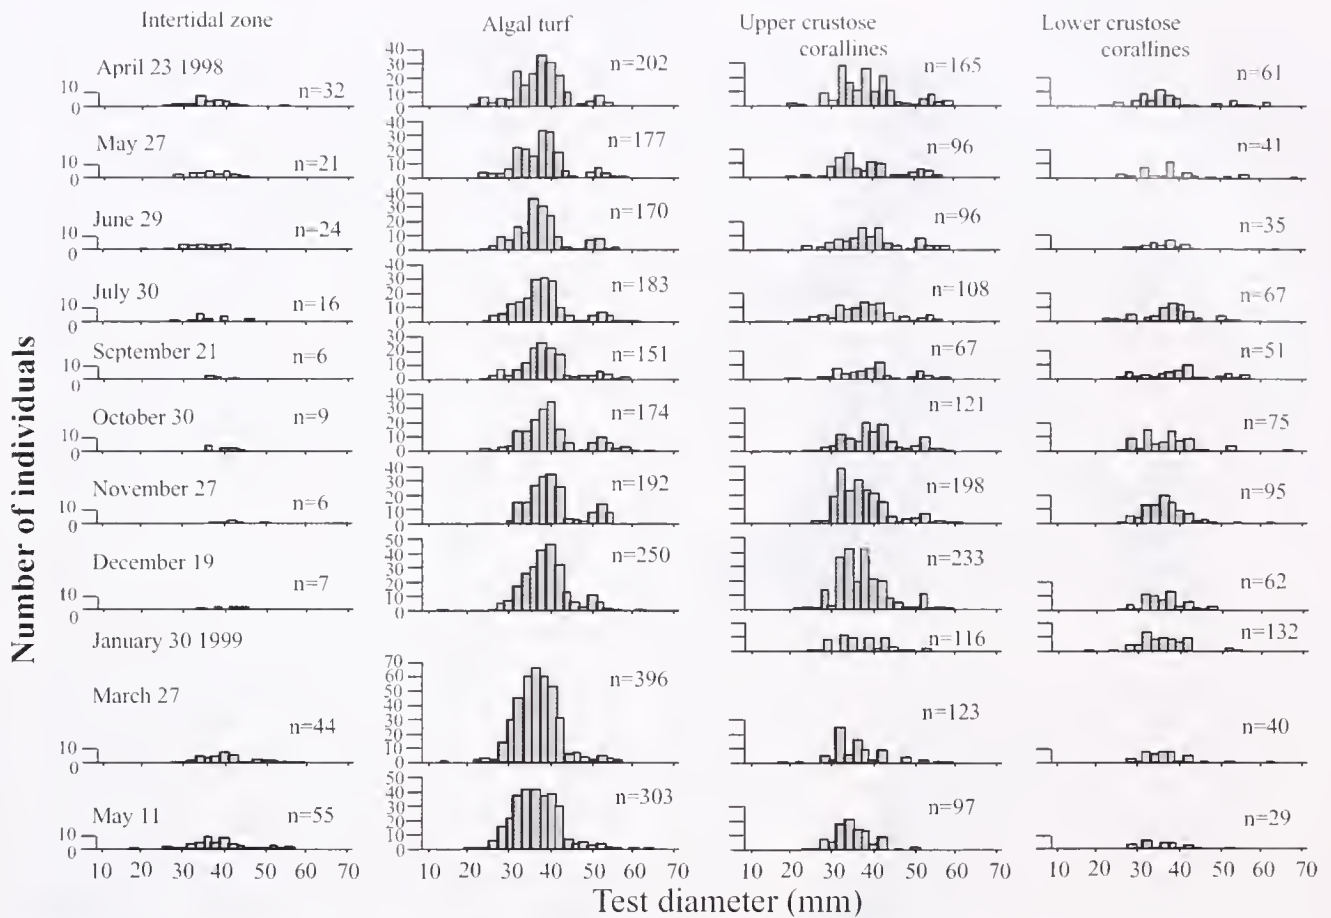

Figure 6. Seasonal changes in the test diameter frequency distribution of *Hemicentrotus pulcherrimus* at the four areas, intertidal zone, algal turf, upper crustose corallines, and lower crustose corallines, at the study site.

Scale bars represent 100 μ m.

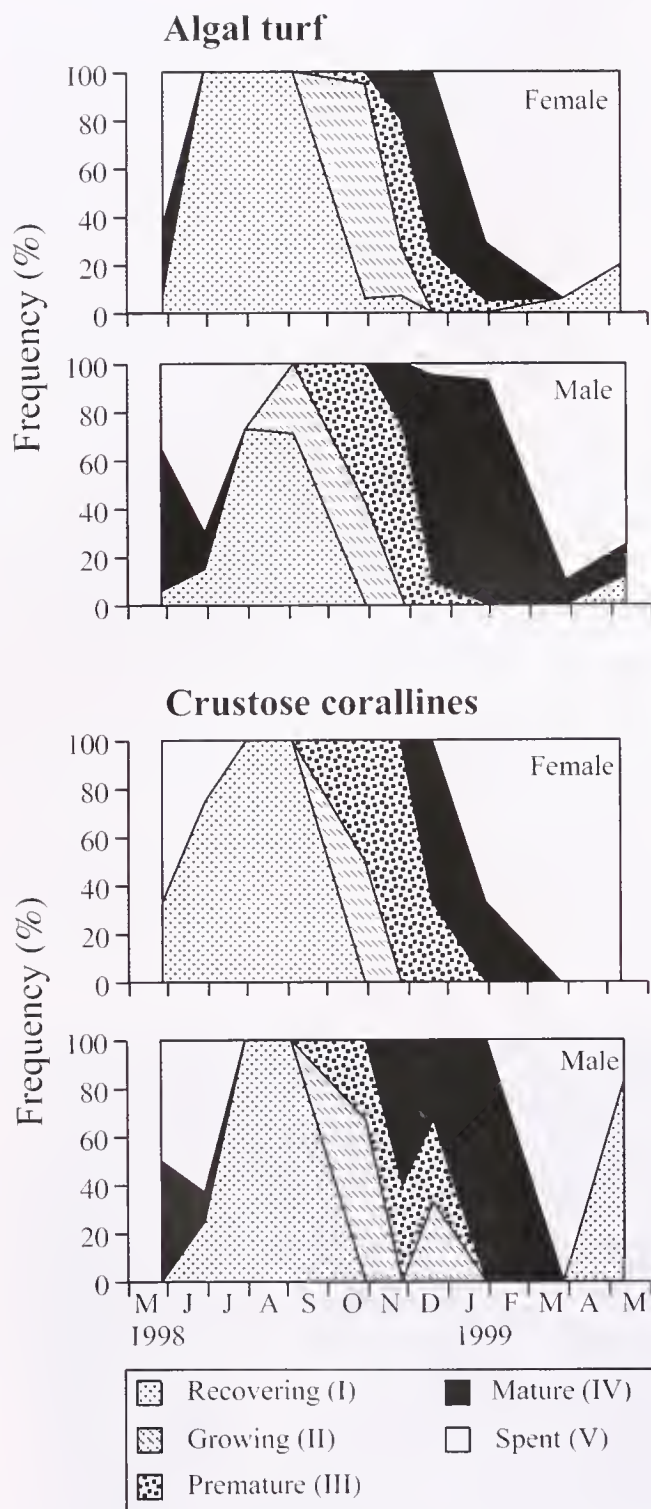

Figure 8. Seasonal changes in the gonad developmental stage of *Hemicentrotus pulcherrimus* at algal turf and crustose corallines.

community are shown in Figure 9. At each community, a significant seasonal difference in gonad indices was found (Algal turf: $df = 9$, $MS = 371.4$, $F = 35.956$, $P < 0.0001$, Crustose coralline: $df = 9$, $MS = 32.1$, $F = 3.968$, $P < 0.0026$). There was no statistical difference in the gonad indices at algal turf from May to

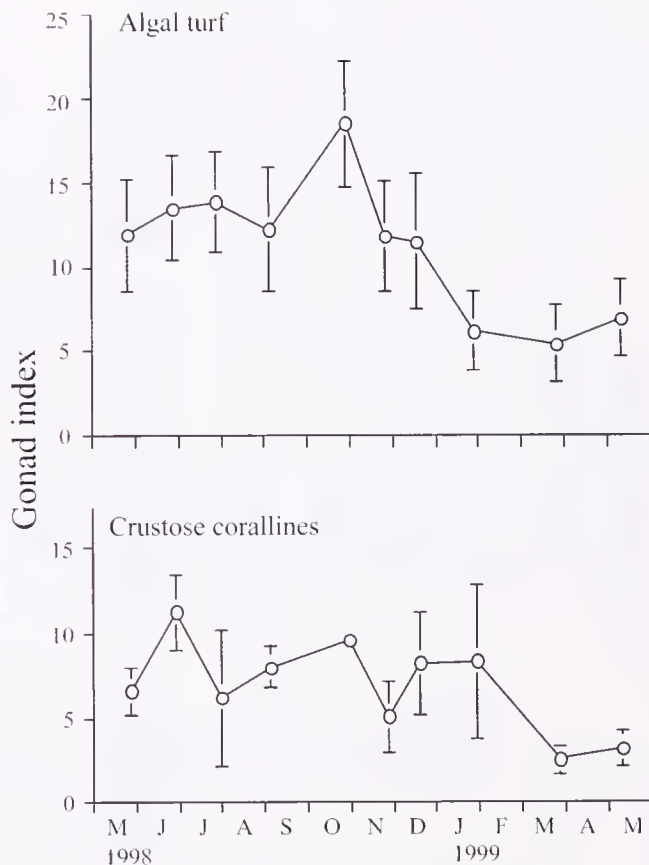

Figure 9. Seasonal changes in the gonad indices of *Hemicentrotus pulcherrimus* at algal turf and crustose corallines. Vertical bars represent standard deviations.

September 1998, when those ranging from 11.9–13.8 were in the recovering stage ($P > 0.05$). Then, the indices significantly rose to 18.5 in October, when gonad development was in the growing and premature stages ($P < 0.01$). The indices significantly fell to the minimum value of 5.4 in March 1999 ($P < 0.05$) and remained at that value until May. The gonad indices on crustose corallines ranged from 5.0–11.2 from May 1998 to January 1999, and no seasonal difference in the indices was found ($P > 0.05$). In March, the indices showed a minimum value of 2.5, similar to those found on algal turf. Except for June, December, and January, the gonad indices on algal turf were higher than those at crustose corallines ($P < 0.05$).

Gut Contents

The gut contents of *H. pulcherrimus* at each algal community are identified as shown in Table 1. In the gut contents of sea urchins on algal turf, the algae of 15 species, 7 genera and 2 unidentified taxa were found. These were small algae, except for *Sargassum* spp. The seagrass *Zosteraceae*, the attached diatom *Bacillariophyceae*, a terrestrial plant, and animals such as *Gastropoda*, *Bivalvia*, and *Crustacea* were also found. In those components, *Sargassum* spp., *Chondrus* spp., *Acrosorium polyneurum*, and *Crustacea* occurred all year round. On crustose corallines, a similar number of species, genera and taxa of algae occurred despite the fact that few algal species grow, and the other compo-

* Residual matters including the unclassified plants and animals, and sand.

nents were similar to those found on algal turf. Crustose coralline, *A. polyneurum*, and Crustacea occurred all year round.

The seasonal changes in the mean weight percentage of each of the 6 main algal components to total gut contents are shown in Figure 10. On algal turf, *Chondrus* spp., *A. polyneurum*, and *Sargassum* spp. showed high percentages, reflecting the dominant vegetation. The percentage of *Chondrus* spp. was high from July to October. From November to March, the percentage of *A. polyneurum* ranged 30% to 40%, higher than that of five other algae. In May 1999, the percentage of *Sargassum* spp. abruptly rose to 49%, in contrast to fall in that of *A. polyneurum*. On crustose corallines, a high percentage of crustose coralline was found all year round; particularly, the percentage reached 49% to 78% from October to May. In June, July and September, that percentage fell to <21%. In June, the percentage of *Sargassum* spp. abruptly rose to 42%, higher than that of other algae. In September, *C. hubbsii* also

showed high percentage. The percentage of crustose coralline in May 1999 was higher than that in May 1998.

DISCUSSION

The densest habitat of *H. pulcherrimus* was found on algal turf at a depth of 0–0.3 m, where boulders dominated. Similarly, a dense distribution beneath boulders in shallow waters is found in other regions in Japan (reviewed by Agatsuma 2001a). However, their low density on crustose corallines at a depth of >1.0 m with boulders shows that the distribution of *H. pulcherrimus* is not restricted by the factor of bottom characteristics alone. The seasonal changes in density suggest that the sea urchins migrate from crustose corallines to algal turf from November to March. Juvenile *H. pulcherrimus* with 0.8–4.5 mm in test diameter were observed in *Amphiroa dilatata* and the roots of *Phyllospadix japonicus* in shallow waters of the Japan Sea, Fukui (Kawana 1938). However,

Figure 10. Seasonal changes in the mean weight percentage of each of six algal species as the main components in the gut contents of *Hemicecentrotus pulcherrimus* at algal turf and crustose corallines.

it is unknown where the larvae settle and metamorphose. The migration from crustose corallines raises the possibility that the larvae settle on crustose corallines, as do *Strongylocentrotus purpuratus* and *S. franciscanus* (Cameron & Schroeter 1980, Rowley 1989), *S. nudus* (Taniguchi et al. 1994, Sano et al. 1998), and *S. droebachiensis* (Balch & Scheibling 2000).

The gonads of *Strongylocentrotus* spp. in a kelp forest grow larger than they do in barren grounds (Agatsuma 2001b, Gonor 1973, Lang & Mann 1976, Pearse 1980, Wharton 1980, Johnson & Mann 1982, Keats et al. 1984, Scheibling & Stephenson 1984, Sivertsen & Hopkins 1995, Meidel & Scheibling 1998). The difference in gonad mass is caused by food availability at each habitat (Lang & Mann 1976, Sivertsen & Hopkins 1995). Meidel & Scheibling (1998) clarified the difference between the food availability of *S. droebachiensis* in kelp (*Laminaria longicollis*) forest and barren grounds from quantitative gut content analysis.

In the present study, gut content analysis showed that the fo-

liose algae *Chondrus* spp., *A. polyneurum*, and *Sargassum* spp. were main foods for *H. pulcherrimus* on algal turf. The high percentage of crustose coralline in the gut contents of the sea urchins on crustose corallines results in lower gonad indices than those on algal turf. From changes in size frequency distributions, seasonal growth was clearly found from June to December. In the gut contents of the sea urchins on crustose corallines during this period, the percentage of crustose coralline was lower than that in other months, as *Sargassum* spp., *Codium hubbsii* and the other algae were supplied as drift algae from shallow waters. It is more likely that those drift algae contribute the growth of the sea urchins on crustose corallines. The down-shift in the modal size of sea urchins on the algal turf during the migration period could be attributed to the immigration of smaller, low-growing ones from crustose corallines in deeper waters. In addition, the growth of sea urchins on algal turf is considered to be mainly supported by *Chondrus* spp., which showed a high weight percentage in the gut contents until October.

The histological observation of gonad and the seasonal changes in gonad indices show that spawning occurs from January to May, reaching a peak from January to March, as it does in other regions in western Japan (Agatsuma 2001a). Gonad size reached a peak corresponding to maturation and spawning from October to March. The rise in the weight percentage of crustose coralline, which was more than approximately 50% in the gut contents of the sea urchins on crustose corallines after September, is related to a decrease in the supply of drift algae from shallow waters. Therefore, these findings suggest that the grazing activity switched to an active and mobile mode, as found in *S. purpuratus* and *S. franciscanus* (Mattison et al. 1977, Russo 1979, Harrold & Reed 1985) and *Evechinus chloroticus* (Andrew & Stocker 1986), and the movement to algal turf in shallow waters was triggered. As *A. polyneurum* grew dominantly from October to March and showed a high percentage in the gut contents, this alga can be considered to be food that ensures gonad development and success in the reproduction of the sea urchins that migrate from crustose corallines to algal turf. Thus, it is suggested that the migration is related to the search for the algal food *A. polyneurum*.

In the meanwhile, the density of *H. pulcherrimus* on algal turf in March 1999 was higher than that in April and May 1998. In addition, the percentage of crustose coralline in the gut contents on crustose corallines in May 1999 was significantly higher than that in May 1998. These results may suggest that much higher water temperatures during winter in 1999 than those of average years reduced the algal communities as found in Oshika Peninsula near the study site in 1980s (Taniguchi 1991), causing algae to subsequently drift, and resulted in the migration of many sea urchins with poor gonad development to shallow waters. For the sympatric sea urchin *S. nudus*, no 0–1-y-old juveniles with a food habit of attached diatoms and small algae migrate from crustose corallines, where larvae settle, to a kelp (*L. religiosa*) forest (Agatsuma 2001b). In the present study, the pattern of migration of juvenile *H. pulcherrimus* is unclear, as few juveniles of test diameter less than 10 mm were observed. Maturation size is considered to be at 26 mm in test diameter in Fukui (Kawana 1938). Whereas, the difference in maturation size among localities and maturation age is unknown. The changes in test diameter distribution may suggest that over 2-y-old urchins with a test diameter of 32–36 mm were the ones that mainly migrated. Thus, it is unclear whether those migrating sea urchins correspond to the first maturation-size group.

After the migration of *H. pulcherrimus*, no return to crustose corallines was observed. The residence of *H. pulcherrimus* on algal turf is likely to be related to food supply, but it additionally ensures a suitable habitat beneath boulders, which reduce the action of the waves. In addition, a study on the morphological characteristics with thick test in relation to attachment strength of the foot tube, and tolerance of test and spine from abrasion would contribute to understanding their adaptation to a habitat in shallower waters. In the areas in Yamaguchi and Kanagawa Prefectures where *H. pulcherrimus* is observed, the large brown algae Sargassaceae and Laminariales grow sympatrically (Agatsuma 2001a). The interactions between specimens of *H. pulcherrimus* and the marine forest should be studied seasonally.

Significant gonad enhancement of *H. pulcherrimus* on algal turf was found from September to October. The maximum gonad index of 18.5 in October coincides with that of 17–19 at the fishing grounds in Saga, where the most rapid growth in western Japan was reported (Ito et al. 1989, Shimazaki et al. 1987), although

lower than that of 25 in Oshoro Bay, Hokkaido (Agatsuma & Nakata 2004). The seasonal growth and gonad enhancement on algal turf are likely to be caused by *Chondrus* spp., which grew dominantly and showed a high percentage in gut contents. Therefore, the dietary effect of *Chondrus* spp. and *A. polyneurum* as the main food for migrating sea urchins on growth and gonad development should be evaluated by means of a rearing experiment.

ADAPTATION OF RAY'S FLUID THIOLYCOLLATE MEDIUM ASSAY TO DETECT AND QUANTIFY PLANKTONIC STAGES OF *PERKINSUS* SPP. PARASITES

REBECCA ELLIN¹ AND DAVID BUSHEK²*

¹North Carolina Coastal Reserve Program, 400 Commerce Avenue, Morehead City, North Carolina 28557; ²Haskin Shellfish Research Laboratory, 6959 Miller Avenue, Port Norris, New Jersey 08349

ABSTRACT The parasites *Perkinsus* spp. are relatively easily and inexpensively detected in host tissues, but available methods to detect free-living planktonic stages are technologically complex and expensive. As a result, few studies have been conducted to detect and quantify free-living stages during transmission. Here, we describe an adaptation of Ray fluid thioglycollate medium (RFTM) assay to detect and enumerate *Perkinsus* spp. parasites in environmental water samples. Recovery of *in vitro* cultured *P. marinus* was successful, but recovery rates were low. Filtration of water samples captured significantly more cultured *P. marinus* cells than centrifugation. Lipid supplementation during RFTM incubation enhanced recovery of cultured *P. marinus*, but not of naturally occurring *Perkinsus* spp. parasites. Comparisons between the modified RFTM filtration method and a more complex immunoassay revealed that the two methodologies were equally sensitive, indicating that the RFTM filtration method may be confidently applied to environmental water samples to determine relative concentrations of *Perkinsus* spp. parasites.

KEY WORDS: *Perkinsus marinus*, dermo, disease, oyster, RFTM, planktonic, filtration

INTRODUCTION

The protozoan parasite *Perkinsus* that are pathogenic to a variety of shellfish worldwide (Bower et al. 1994). Most notable in North America is *Perkinsus marinus* Levine, a protozoan endoparasite that causes dermo disease in the eastern oyster, *Crassostrea virginica* Gmelin. The parasite is common from Maine to Mexico (Krantz & Jordan 1996) and is responsible for mass oyster mortalities in Delaware Bay, Chesapeake Bay, and the Gulf of Mexico (Ford & Tripp 1996). It has long been known that direct transmission of *P. marinus* to *C. virginica* occurs via the water column (Ray 1954), but few attempts have been made to develop and apply methods to detect *P. marinus* in the water column. As a result, knowledge about planktonic stages of *P. marinus* and the processes that affect this important life cycle phase is limited. Applications of an immunoassay (Dungan & Roberson 1993) and the polymerase chain reaction (PCR) in combination with species-specific molecular genetic probes to quantify planktonic stages in environmental water samples have met with varying success (Roberson & Dungan 1994, Yarnall 1998, Ragone Calvo et al. 2003, Audemard et al. 2004). These methods are technologically complex, not readily available to many laboratories and expensive. This study describes the adaptation of Ray fluid thioglycollate medium (RFTM) assays for enumerating planktonic stages of *Perkinsus* spp. parasites from environmental water samples.

Since the discovery of *P. marinus* in the 1940s (Mackin et al. 1950), detection and enumeration methods have focused on categorizing infections within oyster tissue. These methods include histology, tissue smears, the RFTM assay, a polyclonal immunoassay and various molecular genetic probes. Tissue smears and histological methods that were initially used to diagnose infections (Mackin et al. 1950) were soon replaced by the RFTM assay (Ray 1952, 1966). During this assay, the parasite enlarges and develops a thick cell wall that stains blue-black with Lugol's iodine, facilitating its detection. The RFTM assay is easy to perform, inexpensive and sensitive when combined with NaOH digestion of the sample (Choi et al. 1989, Bushek et al. 1994). It is not species-

specific, but it appears to be genus-specific and remains the most commonly used method for detection of *Perkinsus* spp. infections in molluscan hosts (Bower & McGladdery 2003).

The RFTM assay has been adapted to quantify *P. marinus* in tissues (Choi et al. 1989), hemolymph (Gauthier & Fisher 1990), and entire individuals (Bushek et al. 1994, Fisher & Oliver 1996). Of particular relevance to quantifying *P. marinus* and other *Perkinsus* spp. in plankton is the discovery by Choi et al. (1989) that oyster tissues, bacteria and most other contaminants may be digested away with 2M NaOH leaving a suspension of parasites (actually only the cell walls) that may be stained and counted. Fisher and Oliver (1996) demonstrated that NaOH digestion does not affect the thick cell wall that *P. marinus* develops during RFTM incubation. Two assumptions, however, must be made to use the RFTM assay quantitatively. First, all life stages are assumed to enlarge during incubation and to stain with Lugol's iodine for detection (Ray 1952). Early comparisons between the RFTM method and histology revealed that all identifiable stages of *P. marinus* occurring within host oysters enlarged in RFTM (Ray 1954, Stein & Mackin 1957). Additional support for this assumption was provided when Ragone Calvo and Bureson (1994) were unable to detect any previously unknown stages of *P. marinus* with a polyclonal anti *P. marinus* antiserum applied to histological samples. The second assumption is that no proliferation occurs during incubation in RFTM. By monitoring *P. marinus* counts and enlargement throughout incubation in RFTM, Ray (1952) and Stein and Mackin (1957) provided evidence to support this assumption. In addition, extensive efforts to culture *P. marinus* continuously in RFTM were unsuccessful (Ray 1954, Prokop 1950, Mackin & Boswell 1956). Under these assumptions, NaOH digestion of RFTM incubated tissues is routinely used to quantitatively enumerate *P. marinus* in many laboratories.

We applied RFTM incubation and NaOH digestion to environmental water samples as a method to enumerate planktonic stages of *P. marinus*. After initial attempts yielded positive (≤ 5 cells/liter) results, a series of experiments was conducted to determine the efficiency of the method and to identify possible improvements. The goal was to develop a simple, inexpensive method to quantify *P. marinus* from environmental water samples using tools

*Corresponding author. E-mail: bushek@hsrl.rutgers.edu

generally available to laboratories capable of performing standard RFTM assays.

METHODS AND RESULTS

Five experiments were conducted sequentially to examine various aspects of the assay. The first three experiments were performed with *in vitro* cultured *P. marinus* to determine the efficiency of and possible improvements to the method, whereas the latter two experiments examined naturally occurring *P. marinus* in environmental water samples. Because results of each experiment were used in designing subsequent experiments, methods and results are presented together for each experiment. All data were analyzed using SYSTAT statistical software (Wilkinson 1998).

Experiment 1

Centrifugation Versus Filtration

This experiment was designed to determine if there was a difference in recovery of parasite cells collected via centrifugation or filtration. Replicate samples (500 mL) of 1- μ m filtered seawater (FSW) were spiked with 1-mL aliquots of *in vitro* cultured *P. marinus* cells that had been maintained in ATCC 1886 medium (www.atcc.org) with minor modifications described in Bushek et al. (2000). After mixing the parasites in each sample, they were recovered as pellets via centrifugation ($\times 650$ g, $\times 2603$ g, or $\times 5858$ g for 15 min, $n = 2$ per treatment) or filtered (vacuum pressure = 175 mm Hg, $n = 3$) onto a Gelman GN-Metricel 0.45- μ m membrane. Pellets and filters were transferred to 15-mL conical centrifuge tubes containing 10 mL RFTM fortified with 10 μ L of penicillin-streptomycin (Sigma P-0781) to retard bacterial growth. After incubation at room temperature for one week in the dark, the samples were pelleted at $\times 823$ g for 15 min. Centrifuged samples were resuspended in 5 mL 0.2- μ m FSW, stained with Lugol's iodine and placed on a Gelman GN-Metricel Membrane filter paper (0.45 μ m pore size) under 100 \times magnification for enumeration (Fisher & Oliver 1996). Filtered samples were resuspended in 2M NaOH (Choi et al. 1989) to digest the filter (2 h at 60°C), then washed twice in 0.2- μ m FSW, resuspended in 5 mL 0.2- μ m FSW, stained with Lugol's iodine and enumerated with a Hausser counting chamber under 100 \times magnification. The enumeration of filtered samples differed from centrifuged samples because small portions of the filter that remained after digestion obscured the parasites when counted on a Gelman GN-Metricel Membrane filter. The Hausser counting chamber slowed processing because samples were no longer coplanar, but eliminated the problem of filter particulates obscuring parasites. Enumerating all parasites in these samples required focusing through layers of the medium.

In vitro cultured *P. marinus* were recovered and successfully enumerated from all centrifugation and filtration samples. The parasites were more difficult to detect than expected because, compared with parasites in oyster tissues, relatively little enlargement occurred during RFTM incubation, and staining with Lugol's iodine was weak. Although the initial concentration of parasites used to obtain initial aliquots had not been precisely determined, the percentage of cells recovered was much lower than expected, based on earlier cell counts from the *in vitro* cultures. Unfortunately, this oversight precluded an estimate of recovery efficiency. Nevertheless, because equal aliquots from the same parasite suspension were used, it was clear that significantly more parasites were consistently recovered with filtration than with centrifugation

treatments (Tukey, $P < 0.001$, Fig. 1). Centrifugation recovery decreased with increasing centrifugal force; $\times 650$ g centrifugation resulted in a significantly higher parasite recovery than $\times 5858$ g centrifugation (Tukey, $P = 0.018$), but recovery at the intermediate velocity did not differ significantly from either extreme. Logistically, centrifugation was more time consuming than filtration, requiring 45 min to concentrate samples compared with 15 min for filtration. Because filtration was more efficient than centrifugation, subsequent experiments used the filtration method only.

Experiment 2

Recovery Efficiency

This experiment involved a series of treatments designed to measure recovery efficiency and identify potential sources of parasite loss. In addition, because enlargement and staining were lower than expected in Experiment 1, each treatment was duplicated with RFTM that was supplemented 1:100 (v/v) with lipid concentrate (+lipids). Nickens et al. (2002) reported that the addition of lipids may increase enlargement and cell wall development of *in vitro* cultured *P. marinus* during RFTM incubation. The lipids used for supplementation (GIBCO BRL 21900-030) were derived from cod liver oil and supplemented with cholesterol, Pluronic F-68, DL- α -tocopherol acetate and Tween 80. Treatment 1 (water + filter + RFTM) and treatment 2 (water + filter + RFTM + lipids) replicated the entire RFTM filtration methodology used in Experiment 1, except that samples consisted of only 200-mL FSW and were spiked with known concentrations of viable cultured *P. marinus* clones (4.04×10^5 cells of isolate LA22 clone 8, 5.64×10^5 cells of isolate LA25 clone 2, and 3.97×10^5 cells of isolate LA25 clone 4; These isolates were derived from oysters collected from the Gulf coast of Louisiana, USA and provided by J LaPeyre). In treatments 3 (filter + RFTM) and 4 (filter + RFTM + lipids), parasites were added directly to the filter without applying a vacuum. These treatments tested the effects of handling the parasites (i.e., moving parasites from culture medium into seawater and capturing them on the filter). In treatments 5 (RFTM) and 6 (RFTM + lipids), parasites were added directly to RFTM to determine if the filter or NaOH digestion interfered with enlargement and detection of the parasites. Because no filter was used in treat-

Figure 1. Centrifugation ($\times 650$ g, $\times 2603$ g, and $\times 5858$ g) versus filtration (vacuum pressure = 175 mm Hg) of water samples for recovery and enumeration of *P. marinus*. Error bars represent one SEM. Treatments with the same letter are not significantly different at $\alpha = 0.05$.

ments 5 and 6, there was no need to perform the NaOH digestion step.

The percentage of parasites recovered was calculated for each treatment then arcsine transformed to normalize the data for analysis of variance (Sokal & Rohlf 1981). The variables filter, water and lipids were examined for differences in recovery. A treatment involving water but no filter would have completed a 3-way ANOVA; however, this treatment was not possible to test without centrifugation, which would have confounded the experiment. The absence of this treatment resulted in lost degrees of freedom for the 3-way ANOVA. Therefore, the 3-way interaction between filter, water and lipids; and the 2-way interaction between filter and water, were removed as suggested for a fractional factorial design in which data cells are missing (Wilkinson 1998).

The recovery efficiency of the RFTM filtration method used in Experiment 1 (treatment 1) was surprisingly low: $2.71\% \pm 0.42$ (Table 1). Lipid supplementation resulted in significantly higher recovery across all treatments (Table 2, Fig. 2). The addition of lipids increased the number of parasites detected and generally increased the intensity of staining, but did not increase enlargement of the cells. The ANOVA in Table 2 indicated a significant effect of adding the cultured cells to water before capturing them on a filter. Inspection of Figure 2 indicates that treatments 1 and 2, when parasites were first diluted in FSW, resulted in considerably lower recovery than their respective treatments (3 and 4) when parasites were added directly to filters. Recovery was intermediate when parasites were added directly to RFTM (Fig. 2). Because recovery for treatments 5 and 6 was not greater than recovery for other treatments, cell loss was not attributed to effects of NaOH digestion.

Experiment 3

Lipid Dose Effects

This experiment was designed to determine if a higher concentration of lipids would further enhance recovery of *in vitro* cultured *P. marinus*. Nine, 200-mL samples of FSW were spiked with known concentrations of viable cells from one of three discrete *P. marinus* isolates (10.2×10^5 cells of ATCC 50768; 7.53×10^5 cells of ATCC 50889 and 4.57×10^5 cells of ATCC 50776). Lipid dose treatments included no lipids (control), 1:100 (v/v) lipids/RFTM, and 1:10 (v/v) lipids/RFTM. Lipids were added to RFTM prior to sample incubation. Three replicate samples were tested per treatment and a different *P. marinus* isolate was used for each replicate to ensure results were not isolate specific. Water samples were filtered and processed following the procedure outlined in Experi-

TABLE 1.

Recovery efficiency of the RFTM filtration method. Recovery rates for Experiment 2, Treatment 1. The recovery rate for each replicate is indicated.

<i>P. marinus</i> Isolate	<i>P. marinus</i> Added	<i>P. marinus</i> Recovered	Percent Recovery
LA22 - 8	40.4×10^4	1.4×10^4	3.467

Error	12	0.534	0.045		

ment 2, treatment 1. After recovery rates were calculated, a 1-way ANOVA and a control versus lipid contrast were used to examine lipid dose effects.

Results showed that both lipid dosage treatments recovered more parasites than the control (Fig. 3), but the increase was not significant (1-way ANOVA, $P = 0.555$). A contrast of control versus lipid treatments was also not significant ($P = 0.346$). Although not significant, recovery was lower for the higher lipid concentration. Recovery in the 1:100 treatment was similar to treatment 2 in Experiment 2. That is, variability within treatments was high and may be attributed to lipid addition, differences between the *P. marinus* isolates, or both. Additional experiments that include more isolates than were available at the time of these experiments are needed to resolve the source of variation.

Experiment 4

Environmental Water Sample Enumeration and Lipid Dose Effects

This experiment was essentially identical to Experiment 3, but the methods were applied to environmental water samples rather than *in vitro* cultured *P. marinus*. Three environmental water samples (500-mL each) were collected August 22, 1998 from Oyster Landing, North Inlet, South Carolina using two automated

Figure 2. *Perkinsus marinus* cell recovery for treatments in Experiment 2. Parasites were diluted in FSW then filtered in treatments 1 and 2, added directly to filters for treatments 3 and 4, and added directly to RFTM for treatments 5 and 6. A 1% lipid supplement (1:100 v/v) to RFTM was added to Treatments 2, 4, and 6. Data are means \pm SEM of three replicates.

Figure 3. Lipid dose effects on cultured *P. marinus* cell recovery. Three lipid concentrations were tested: control = no lipids, 1:100 (v/v) lipids/RFTM, and 1:10 (v/v) lipids/RFTM. Data are means \pm SEM of three discrete clones for each treatment. No significant differences existed among treatments ($P = 0.555$).

ISCO water samplers. Each sample was prefiltered through a 25- μ m nylon mesh, divided into three equal aliquots, and then processed as described for Experiment 3 using the same lipid treatments. Because *P. marinus* is the only species of *Perkinsus* that has been documented to occur in South Carolina (Reece et al. 1997, 2001), all cells positive per the RFTM assay were considered to be *P. marinus*. Counts were standardized to parasites per liter and then \log_{10} -transformed to normalize the distribution for a 1-way ANOVA (Sokal & Rohlf 1981). Tukey multiple comparisons were used to differentiate significance levels among treatments, and a control versus lipid contrast was calculated to test the effect of adding lipids.

Unambiguous positives were obtained from all environmental water samples. Cells were easily detected and enumerated, ranged in size from 10–35 μ m, and stained blue-black with Lugol's iodine. A 1-way ANOVA revealed a significant difference between the environmental water sample lipid dose treatments ($P = 0.001$). The 1:100 (v/v) lipid treatment recovered significantly more parasites than the 1:10 (v/v) lipid treatment (141 ± 19 cells L^{-1} versus 3 ± 2 cells L^{-1} , Tukey $P = 0.001$), but not significantly more than the no-lipid control (89 ± 34 cells L^{-1} , Tukey $P > 0.05$). The control treatment also produced a recovery rate significantly greater than the 1:10 (v/v) lipid treatment (Tukey $P = 0.003$). A contrast comparing the control versus both lipid treatments was significant ($P = 0.030$); however, as a result of the low recovery in the 1:10 treatment the combined lipid effect was to decrease recovery compared with the control. These data indicate that 10% (v/v) lipid additions may inhibit recovery. Variability across the treatments was low compared with Experiments 2 and 3.

Experiment 5

Comparison of RFTM Filtration and Immunoassay Methods

Prior to this work, the only other attempts to enumerate planktonic stages of *P. marinus* used a polyclonal immunoassay with near genus-level specificity (Roberson & Dungan 1994, Ragone Calvo et al. 2003, but see Bushek et al. 2002). The present experiment was conducted to compare detection of planktonic *P. mari-*

inus via the polyclonal immunoassay and the RFTM filtration methods. Paired environmental water samples (500-mL) were collected September 26, 1998 from Oyster Landing, North Inlet, South Carolina using two automated ISCO water samplers. The paired samples were processed using the RFTM filtration and the immunoassay methods. All samples were prefiltered through 25- μ m nylon mesh. RFTM samples were processed as described for Experiment 2, treatment 1. The immunoassay samples were processed using methods described by Bushek et al. (2002), which is a modification of the protocol described by Dungan and Roberson (1993). Briefly, the samples were concentrated at $\times 100$ g for 15 min and resuspended in sterile FSW with 10% buffered formalin. Particulates were then captured on a 1.0- μ m pore size black polycarbonate filter in a Swinnex-13 membrane filter unit, washed three times with phosphate buffered saline (PBS), blocked with a blocking buffer for 30 min and then washed with phosphate buffered saline containing Tween-20 (PBST). The primary antibody (rabbit anti-*P. marinus*) was applied for 30 min then washed with PBST before the secondary antibody (goat antirabbit-FITC) was applied. After 30 min, the sample was washed with PBST, counterstained with Evan blue, washed with PBS, and finally mounted on slides to enumerate parasites via epifluorescence microscopy. Using this procedure, the nucleus of any *Perkinsus* spp. parasites present fluoresced bright green, making them distinguishable from other cells and debris. Counts from both the immunoassay and RFTM assays were standardized to parasite cells per liter and results were compared using a paired *t*-test.

The RFTM and immunoassay methodologies for enumeration of *Perkinsus* spp. parasites were not significantly different (Paired *t*-test for means $P = 0.411$, Table 3). This indicated that both methods were equally sensitive.

DISCUSSION

In contrast to Yarnall et al. (2000), we successfully detected and enumerated *P. marinus* in samples collected from enzootic waters using standard RFTM methods. Yarnall (1998) reveals that Yarnall et al. (2000) used centrifugation to concentrate their samples in which their PCR assays did not yield enough DNA for quantitation. Interestingly, a nearby contemporaneous study using a flow cytometric immunoassay estimated planktonic *P. marinus* concentrations of 200–400 parasites L^{-1} (Ragone Calvo et al. 2003). Our comparison of detection via RFTM versus the immunoassay indicated that both methods were equally sensitive when applied to environmental water samples. In this study, centrifuga-

tion was less efficient than filtration, which may account for the lack of detection by Yarnall et al. (2000) when results from Ragone Calvo et al. (2003) indicated that the parasite was abundant. A more recent study using improved molecular genetic tools was able to quantify *P. marinus* with PCR methods from the same area as the Yarnall et al. (2000) study (Audemard et al. 2004).

It should be noted that the RFTM and immunoassay methods are genus-specific and may detect other species if present. Hence, as species-specific molecular methods become more widely available (e.g., Audemard et al. 2004) they may be necessary where multiple species occur. It may also be valuable to compare species-specific and genus-specific methods in samples collected over space and time. Such experiments will provide insight into the inter and intragenus cross-reactivity of the methods as well as the co-occurrence of *Perkinsus* species.

The low recovery of *in vitro* cultured parasites in this study was disconcerting, but may not be relevant to enumerating *Perkinsus* spp. abundances from environmental samples. Compared with parasites obtained from infected hosts, it was clear that cultured cells did not enlarge or stain well after incubation in RFTM. This difference indicates that *in vitro* cultured *P. marinus* cells are physiologically different from cells harvested from infected hosts. Bushek et al. (1997) found that *in vitro* cultured cells appeared to have a reduced ability to survive injection into oysters, and Ford et al. (2002) clearly demonstrated a reduction in virulence following *in vitro* culture using the same culture methods used in the present study. Our attempts to identify steps in the methodology that account for cell loss were largely unsuccessful, leading us to the conclusion that cell loss is largely a result of handling the cells, possibly from the shock experienced by cells when transferred from culture medium to FSW. This may partly explain the loss of virulence reported by Ford et al. (2002), as they similarly transferred parasites from culture medium to seawater and then into hosts. Interestingly, enlargement, staining and recovery of cultured *P. marinus* improved with the addition of lipids (1:100 v/v); albeit not always significantly, indicating potential deficiencies in the culture medium. Regardless, the RFTM assay and an independent polyclonal immunoassay performed similarly with environmental samples indicating approximately equal detection efficiencies.

Based on the earlier results and discussion, the RFTM filtration method is a simple, inexpensive method for enumerating *Perkinsus* spp. parasites in environmental water samples. Several additional refinements of the method have resulted in a simpler and less time-consuming RFTM filtration method (Fig. 4). Specifically, washing and resuspension of the pelleted, NaOH-hydrolyzed samples in deionized water rather than FSW was convenient, efficient and did not affect sample storage (Gauthier & Fisher 1990). In addition, stained samples may be read on a Hausser counting chamber at 40 \times magnification instead of 100 \times magnification because the natural cells enlarge more during RFTM incubation than *in vitro* cultured cells, stain characteristically and are easily observed under 40 \times magnification. This dramatically decreased the time required to scan the counting chamber. Lipids were not added to the final protocol because it was not clear from the results of Experiments 3 and 4 that lipids actually improved the overall recovery of planktonic parasites because of the high variability and reduced recovery in 1:10 (v/v) lipids/RFTM samples.

Direct water borne transmission of *P. marinus* was discovered more than 50 y ago (Ray 1954), yet little is known about the free-living stages of this or any other *Perkinsus* species that afflict various molluscs around the globe. As these protozoan pathogens

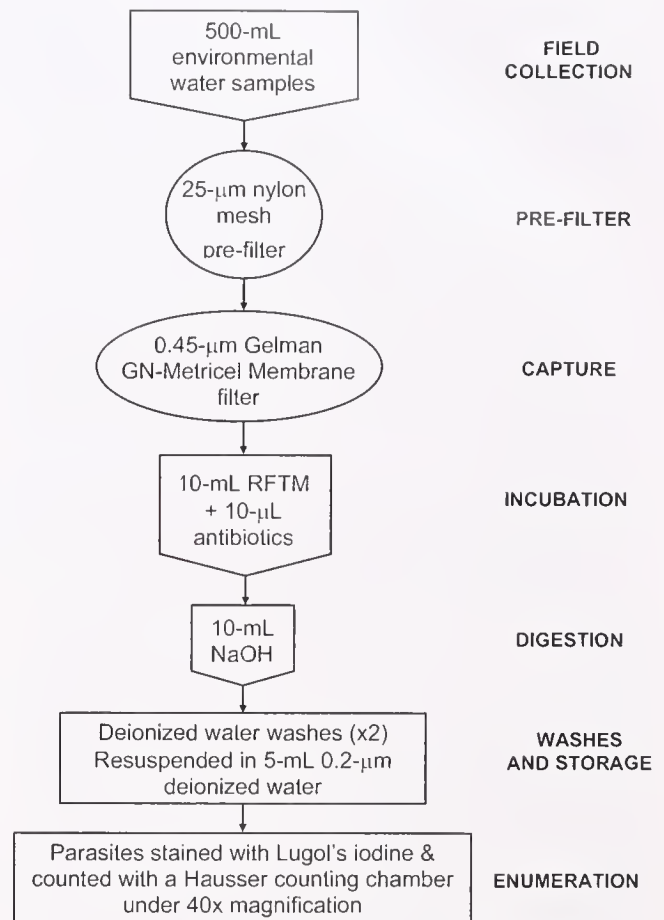

Figure 4. Flow chart of the adopted RFTM filtration method.

continue to plague shellfisheries, the need to better understand their dispersal and transmission dynamics continues to grow. A thorough understanding of these dynamics can be achieved only through investigations exploring the timing and fate of free-living planktonic stages during transmission. The experiments discussed in this study outline a simple method to detect and enumerate planktonic stages of *Perkinsus* spp. The method adapts the well-known and extensively applied RFTM method that is known to detect all species of the genus *Perkinsus*. Hence, the method should be readily accessible to most laboratories that already use RFTM assays. Whereas the RFTM filtration method provides a simple and inexpensive methodology for enumerating *P. marinus* in environmental water samples, the absolute efficiency of the method remains questionable. Nonetheless, the RFTM filtration method may be used to indicate relative differences in parasite numbers.

ACKNOWLEDGMENTS

The authors thank K Hudson for assistance with culturing *P. marinus* isolates. M Chintala and J LaPeyre provided some of the isolates and C Dungan provided several discerning comments in developing these experiments. Funding for this research was provided by NSF-RUI Project #DEB-950957, and South Carolina Sea Grant Consortium ODRP Project R/OD-1.

COMPARISON OF TECHNIQUES FOR DIAGNOSIS OF BROWN RING DISEASE AND DETECTION OF *VIBRIO TAPETIS* IN THE MANILA CLAM, *VENERUPIS (RUDITAPES) PHILIPPINARUM*

ABSTRACT The bacterium, *Vibrio tapetis*, is the aetiological agent of Brown Ring Disease (BRD), which affects the Manila clam, *Venerupis (Ruditapes) philippinarum*. Two PCR assays for detection of *V. tapetis* were applied to a sample of 52 Manila clams, and evaluated in comparison with the more traditional *V. tapetis* detection method of microbiological isolation and characterization, as well as the traditional BRD diagnostic technique of shell valve analysis. The pathogen was detected in 15.4% of the sample using the PCR assay of Rodríguez et al. (2003, 2006) in 50% of the sample using the PCR assay of Paillard et al. (2006) and in 36.5% of the sample by microbiological methods. Whereas shell valve analysis was the least sensitive technique, detecting BRD in 7.7% of the sample, it was an essential diagnostic tool because it was the only technique that identified the disease, rather than the aetiological agent. None of the four techniques was sufficient on its own for effective BRD diagnosis; rather various combinations of two techniques were the minimum required. The combination of shell valve analysis with the assay of Paillard et al. (2006) proved to be the most sensitive and rapid of those tested. Shell valve analysis was the most time-efficient and cost-effective technique, whereas microbiological characterization was the most time-consuming, and PCR detection, using either set of primers, the most expensive. These results may need to be considered in light of diagnosis and management of BRD.

KEY WORDS: brown ring disease, *Vibrio tapetis*, *Venerupis (Ruditapes) philippinarum*, diagnostics, PCR, microbiology

INTRODUCTION

The Manila clam, *Venerupis (Ruditapes) philippinarum* (Adams & Reeve, 1850), is the second most important cultivated mollusc species in the world, contributing 20% of the total world aquaculture production of molluscs (FAO 2002). Globally, production of the Manila clam has increased by 60% from 1997 to 2002 (FAO 2002). In Europe, production takes place predominantly in Italy, France, Spain and the United Kingdom. Ireland's Manila clam production, though small, has been steadily increasing in recent years, with an output of 181 tons achieved in 2004 (Parsons 2005). The increase in production worldwide, with its concentration of large quantities of clams in confined areas, has facilitated the proliferation of pathogens such as *Perkinsus* sp. (in Asia) (Park & Choi 2001, Park et al. 2006a) and *Vibrio tapetis* (in Europe and Asia) (Paillard 2004, Park et al. 2006b). Consequently, there is a need for rapid, effective and accurate techniques for the diagnosis of Manila clam diseases.

Brown ring disease (BRD) caused by the bacterial pathogen, *V. tapetis*, is not regulated for disease control under existing European Union (EU) legislation, nor is it a disease notifiable to the Office International des Epizooties (OIE). Nevertheless, since the early 1990s, it has been responsible for mass mortalities in the clam cultivation industry in Europe, and has been diagnosed from the majority of clam cultivation areas (Paillard & Maes 1990, Castro et al. 1992, Paillard et al. 1994, Robledo et al. 1994, Castro et al. 1995, Figueras et al. 1996, Castro et al. 1997, Novoa et al. 1998, Clarke 1999, Allam et al. 2000b).

Diagnostic methods for BRD have traditionally involved examination of the interior shell valves for analysis of conchiolin deposition, as described by Paillard & Maes (1994). Histopathology is not useful for BRD diagnosis because tissue lesions are not systematically observed in diseased clams (Paillard et al. 1994) and alterations of the digestive gland and mantle are observed only

in the more advanced stages of the disease (Plana & Le Pennec 1991, Paillard et al. 1994, Paillard 2004). Notwithstanding the analysis of shell valves for BRD signs, all other diagnostic techniques focus on detection of the aetiological agent, *V. tapetis*, rather than the disease itself. Bacteriological isolation procedures are in place and have resulted in the isolation of *V. tapetis* from BRD-affected clams from France, England and Galicia, northwestern Spain (Paillard & Maes 1990, Borrego et al. 1996, Novoa et al. 1998, Allam et al. 2000b). An immunological assay was developed in southwestern Spain, which demonstrated that *V. tapetis* was the aetiological agent of BRD in this region (Castro et al. 1997). An enzyme-linked immunoassay (ELISA), using monoclonal antibodies, which react specifically with *V. tapetis*, is also available for identification of the bacterium (Noel et al. 1996).

Molecular techniques are now available for detection of *V. tapetis*, in the form of two polymerase chain reaction (PCR) assays, each of which amplifies a specific target region of *V. tapetis* DNA (Rodríguez et al. 2003, 2006, Paillard et al. 2006). Previous studies on other pathogens in other bivalves have indicated that PCR amplification has the ability to detect a higher prevalence of a pathogen than traditional diagnostic methods (Carnegie et al. 2000, Harwood et al. 2004, Lynch et al. 2006).

The aims of this study were to apply *V. tapetis*-specific PCR assays for *V. tapetis* detection and to evaluate them against the more traditional detection method of microbiological isolation and characterization, as well as the traditional BRD diagnostic technique of shell valve analysis; and to assess which technique, or combination of techniques, is most suitable for BRD diagnosis and *V. tapetis* detection in terms of efficiency of detection, time required and cost-effectiveness.

MATERIALS AND METHODS

Clams

A sample of 52 clams, of 25–30 mm in length, was obtained from Mulroy Bay, Donegal, northwest Ireland, in April 2005, from

*Corresponding author. E-mail: l.drummond@ucc.ie

a cultured stock in which BRD was suspected. Clams were placed in a cold room at 4°C prior to dissection, to encourage relaxation of their adductor muscles, for easier opening of the shell valves. After opening of the valves, over 200 µL of extrapallial fluid (EPF) was extracted from each individual by inserting a needle between the mantle and interior shell valve. The EPF was placed in a labeled eppendorf tube. The soft parts of the animal were discarded. The shell valves were retained, labeled and left to dry for 24 h.

Macroscopic and Microscopic Analysis of BRD on Shell Valves

The stage of progression of BRD on the shell valves was monitored according to the classification system of Paillard & Maes (1994), in which the syndrome is characterized by two stages, which may occur simultaneously in a given individual: a conchiolin deposit stage (CDS), in which layers of an organic conchiolin deposit are laid down between the mantle edge and periostracal lamina, and a shell repair stage (SRS), in which the clam lays down layers of shell on top of the conchiolin deposit, for repair and recovery from the disease. CDS index is based on the use of a scale, which takes into account the extent and thickness of the brown ring deposit. For example, CDS 1 (Stage 1) is not visible to the naked eye and can be seen only with a microscope. CDS 2 (Stage 2) corresponds to a limited deposit and CDS 3 through to CDS 7 to more extensive deposits on the inner shell surfaces. Three stages of shell repair are defined: SRS 1 corresponds to the initial accumulation of calcified material; SRS 2 to the partial covering of the deposit by wide calcified plates and SRS 3 to the completely covering of the deposit by shell layers. When the processes of conchiolin deposition (CDS) and shell repair (SRS) are considered together, three phases of the disease are defined: Phase 1 corresponds to development of the disease and is characterized only by accumulation of conchiolin; Phase 2 is characterized by the simultaneous occurrence of both processes in a given individual; and Phase 3 corresponds to the end of the recovery process, when the individual has completely covered the conchiolin deposit (Paillard & Maes 1994).

Microbiological Isolation and Characterization of *Vibrio tapetis*

One-hundred micro liters of EPF from each individual was spread, using a "hockey stick" spreader, on a Thiosulfate Citrate Bile Sucrose (TCBS) (Oxoid Ltd.) agar plate and incubated for 24 h at 18°C. TCBS agar is selective for *Vibrio* species: *V. tapetis* is saccharose-negative on TCBS agar and, as such, appears as a green colony. Four green, saccharose-negative colonies from each TCBS plate were selected and isolated on marine agar to obtain pure cultures. They were subsequently stored in vials of 15% glycerol/85% marine broth at -80°C until further characterization. All the remaining colonies were collected from each TCBS plate, placed in eppendorf tubes containing 1 mL sterile distilled water (in order that each tube contained the colonies of an individual clam) and stored at -20°C until further analysis by PCR.

Isolated colonies were characterized by a series of standard morphological, physiological and biochemical tests (Cowan 1974, Smibert & Krieg 1981, West & Colwell 1984, Borrego et al. 1996). All biochemical tests were performed using marine agar (DIFCO) unless otherwise stated and the incubation temperature was 18 ± 1°C unless otherwise stated. The tests, and the criteria for characterization as *V. tapetis*, are listed in Table 1. The ingredients and recipes used in each test are described in Appendix 3. The type *V. tapetis* strain, CECT 4600 was used as a positive control for all

tests. Isolates, which did not meet the *V. tapetis* criteria, were eliminated from further tests as results became available. Colonies that met the requirements for characterization as *V. tapetis*, had their identities confirmed by PCR detection of *V. tapetis* DNA (Rodríguez et al. 2003, 2006).

PCR Detection of *Vibrio tapetis*

Two PCR assays were used for the detection of *V. tapetis*: the first, developed by Rodríguez et al. (2003, 2006), uses template DNA extracted from bacterial colonies, and the second, developed by Paillard et al. (2006), employs template DNA extracted from the EPF of clams.

Rodríguez Assay (2003, 2006)

Colonies from TCBS plates, in suspension in sterile distilled water, were thawed. DNA from individual clams was extracted using InstaGene Matrix (BIO-RAD) according to manufacturers' instructions and stored at -20°C until required for PCR reactions. PCR amplification of template DNA (at a concentration of 1-3 µg) was undertaken using one Pure Taq Ready-To-Go PCR Bead (Amersham Biosciences) in every reaction: each bead contained 1.5 units of Taq polymerase, 10 mM Tris-HCl (pH 9.0), 50 mM KCl, 1 mM MgCl₂ and 200 mM each dNTP. For a 25-µL reaction, the bead was combined with 2 pmol (1 µL) of forward primer, 2 pmol (1 µL) of reverse primer, 22 µL of sterile distilled water and 1 µL of DNA template solution. DNA from *V. tapetis* CECT 4600 was used as a positive control and distilled deionized water was used as a negative control. Amplification was performed in a Hybaid thermal cycler programmed as follows: an initial denaturation step at

94°C for 3 min; 35 cycles of 94°C for 60 sec, 64°C for 60 sec and 72°C for 90 sec; and a final cycle of 72°C for 5 min. The PCR products were electrophoresed on a 2% agarose gel, stained with ethidium bromide and photographed under UV light. A 50–2,000 bp ladder (Sigma Chemical Company) was used as a molecular marker. In cases where either the positive or negative control was not confirmed by PCR as positive and negative respectively, the results were discarded and the analysis repeated. PCR results were graded as either negative or positive.

Paillard Assay (2006)

DNA was extracted from 100 µL of EPF, of each of the 52 clams, using the chelex method (Saulnier et al. 2000). PCR reactions were carried out in a total volume of 50 µL, including 10 mM Tris-Cl, 50 mM KCl containing 200 µM of each dNTP, 1.5 mM MgCl₂, 400 µM of each primer, VtF and VtR, 0.2U of Taq DNA polymerase (Sigma) and 200 ng of genomic DNA (5 µL of template DNA). DNA from *V. tapetis* CECT 4600 was used as a positive control and distilled deionized water was used as a negative control. PCR amplification was performed in a Hybaid thermal cycler and the thermal cycle consisted of an initial denaturation step at 94°C for 3 min, followed by 35 cycles of 94°C for 60 sec, 63°C for 60 sec and 72°C for 45 sec. The PCR products were electrophoresed on a 2% agarose gel, stained with ethidium bromide and photographed under UV light. A 50–2,000 bp ladder (Sigma Chemical Company) was used as a molecular marker. In cases where either the positive or negative control was not confirmed by PCR as positive and negative respectively, the results were discarded and the analysis repeated. PCR results were graded as either negative or positive.

Comparison of Techniques for Diagnosis of BRD and Detection of *Vibrio tapetis*

The results of screening for BRD by shell analysis, *V. tapetis* detection by bacteriological techniques and *V. tapetis* detection by two PCR assays were subsequently compared. A chi-square test was used to ascertain if there were significant differences in the detection rate between each diagnostic technique.

RESULTS

Macroscopic and Microscopic Analysis of BRD on Shell Valves

Prevalence of BRD in the sample of 52 clams was 7.7% as classified by the system of Paillard & Maes (1994); 48 did not

exhibit BRD symptoms. Of the four symptomatic clams, one displayed CDS 2 and no shell repair, and so was in Phase 1 of BRD; two clams exhibited CDS 3 and SRS 1, and thus were in Phase 2 of BRD and the fourth clam showed CDS 5 and SRS 1 and was thus also in Phase 2 of BRD. Two (50%) were BRD/*V. tapetis*-positive by other diagnostic techniques: Table 2 shows that none of the shell analysis positives were detected by microbiology; one was detected by the Rodríguez assay and two were detected by the Paillard assay. There appeared to be no correlation between stage of disease and detection by other techniques; the clam displaying CDS 5 and one of the clams displaying CDS 3 were not detected as positive by any of the other methods; the second clam exhibiting CDS 3 was positive by both PCR assays; whereas the individual showing CDS 2 was positive by the Paillard assay. Two (50%) of the animals positive by shell analysis were not detected as positive by any other technique. Of 48 animals negative by shell analysis, 31 (64.6%) were deemed positive by one or more of the other techniques.

Microbiological Isolation and Characterization of *Vibrio tapetis*

From 52 TCBS plates, each plate representing an individual clam, a total of 208 suspected *Vibrio* colonies were isolated. After salt and temperature tests (Table 1), 162 colonies were eliminated. Following characterization by the remaining tests, a total of 23 isolates from 19 individuals were identified as *V. tapetis*. Sixteen of the 23 (70%) isolates were derived from individual clams, whereas two isolates originated from each of two clams, and three isolates originated from one individual. Overall, *V. tapetis* was detected in 19 individuals (36.5%) of the sample, 13 (68%) of which were also detected by at least one other technique. Table 2 shows that none of the microbiology *V. tapetis*-positive individuals was positive by BRD shell analysis, three were positive by the Rodríguez assay and 13 by the Paillard assay. Six (32%) of the microbiology positives were not detected by any of the other techniques and 17 (52%) microbiology negatives were deemed positive by one or more techniques.

PCR Detection of *Vibrio tapetis*

Rodríguez Assay (2003; 2006)

V. tapetis was detected in 15.4% (8 individuals) of the sample. Six (75%) of these positives were also positive by other diagnostic methods, of which, one was detected by BRD shell analysis; three by microbiology; and six by the Paillard assay (Table 2). Twenty-

six (59%) of the negatives by the Rodríguez assay were not confirmed by any of the other techniques.

Paillard Assay (2006)

V. tapetis was detected in 50% (26 individuals) of the sample. Seventeen (65%) of the 26 positives were confirmed by other diagnostic methods, of which 2 were detected by BRD shell analysis; 13 by microbiology and 6 by the Rodríguez assay (Table 2). Nine (35%) Paillard PCR-positives were not detected by any other technique and 10 (39%), which were negative by the Paillard assay were detected as positive by one or more of the other techniques.

Comparison of Techniques for Diagnosis of BRD and Detection of *Vibrio tapetis*

The four techniques detected BRD and *V. tapetis* at different levels within the same sample (Table 3) and there was a significant difference between the numbers of BRD/*V. tapetis* positives and negatives detected by the four methods ($\chi^2_3 = 29.45$, $P < 0.001$). BRD prevalence detected by shell analysis was 7.7%; *V. tapetis* detection by isolation and characterization was 36.5%; and by the primers of Rodríguez et al. (2003, 2006) and Paillard et al. (2006) was 15.4% and 50% respectively. When two diagnostic techniques were applied, detection levels ranging from 21.2% to 61.5% were revealed: a combination of BRD shell analysis and PCR by Rodríguez et al. (2003; 2006) produced the lowest detection levels at 21.2%, whereas the combination of microbiological characterization and PCR by Paillard et al. (2006) produced the highest detection levels at 61.5%. Applications of three techniques led to detection levels ranging from 51.9% to 65.4%, and finally, a combination of all four techniques detected the highest levels of BRD/*V. tapetis* (i.e., 69.2%).

Shell valve analysis was found to be the most cost-efficient technique; only a microscope was required. Microbiological meth-

ods entailed the cost of a wide variety of reagents and media; but the most expensive techniques were *V. tapetis* detection by PCR. With regards to time-efficiency, BRD diagnosis by shell analysis of 52 clams was completed in less than two hours. Only four individuals were BRD-positive and the time taken would be expected to be longer in samples containing a higher percentage of diseased individuals, because of the time required to establish the CDS and SRS of each individual. PCR detection by the Paillard et al. (2006) primer was the next most time-efficient method, with the whole process from DNA extraction through to the visualization of PCR products on an electrophoretic gel taking less than 10 h. The Rodríguez et al. (2003; 2006) assay entailed growth of bacterial colonies on TCBS agar prior to DNA extraction and this added a further 24–48 h to the process. By far the most time-consuming technique was the bacteriological method, which required much preparatory and manipulative work. Additionally, *V. tapetis* colonies require approximately 24–48 h growth on agar media for isolation and the same time or longer for the characterization tests that follow. In this study, the procedure from colony isolation from the extrapallial fluid through to characterization as *V. tapetis* took 5–6 days to complete for any one bacterial isolate.

DISCUSSION

Developments in molecular biology have led to new methods for diagnosing shellfish diseases. The advantages of molecular techniques such as PCR are that they are potentially faster and more sensitive than methods such as culture, serology and histology that are traditionally used to identify shellfish diseases (Cunningham 2002). The currently available PCR primers for detection of *V. tapetis* in clam tissue differed significantly in detection rate with the primers by Rodríguez et al. (2003, 2006) detecting fewer positives (15.4%) than those by Paillard et al. (2006) (50%). Optimization of reaction conditions for the Rodríguez primers was required prior to use, but not for the Paillard primers. However, this optimization may have been necessary because of geographic variation in *V. tapetis* strain (Romalde et al. 2002, Paillard et al. 2006) and perhaps the strain detected in Mulroy Bay was more amenable to detection by the Paillard assay than by the Rodríguez assay. The two sets of primers also differed with respect to their source DNA material: the Paillard primers were applied to the clam's EPF, whereas the Rodríguez primers were applied to DNA from bacterial colonies. Culture of *V. tapetis* is often met with variable success, depending on the stability of culture conditions and the composition of the microbiota and could possibly have compounded the lower detection rate of the Rodríguez assay. Overall, *V. tapetis* detection by PCR was the fastest technique used in the current study, thus making it suitable for situations in which a rapid diagnosis is required. Because PCR is used to amplify certain regions of DNA, it can also achieve significant increases in the sensitivity of detection (McPherson et al. 1991). This was demonstrated by the Paillard assay, which was the single most sensitive assay, capable of detecting *V. tapetis* levels down to 10^2 cfu mL⁻¹ (Paillard et al. 2006).

In this study, nine PCR-positives by the Paillard assay and two by the Rodríguez assay went undetected by any one of the other techniques and could potentially have signified false positives. One of the limitations of PCR is that when used in disease diagnosis, false positives identifying DNA similar to, but not of, the target organism can occur, because of low specificity of the primers. To ensure the greatest possible specificity of PCR primers to

TABLE 3.

A comparison of the efficiency of detection of BRD/*Vibrio tapetis* in a sample of 52 *Venerupis (Ruditapes) philippinarum* by different techniques, individually and in combination.

Technique/Combination of Techniques	Percentage Detection
BRD shell analysis	7.7
Microbiological characterization	36.5
Rodríguez assay	15.4
Paillard assay	50
BRD shell analysis + Microbiological characterization	44.2
BRD shell analysis + Rodríguez assay	21.2

Microbiological characterization + Rodríguez assay	46.1
Microbiological characterisation + Paillard assay	61.5
Rodríguez assay + Paillard assay	53.8
BRD shell analysis + Microbiological characterization + Rodríguez assay	51.9
BRD shell analysis + Microbiological characterization + Paillard assay	65.4
BRD shell analysis + Rodríguez assay + Paillard assay	57.7
Microbiological characterization + Rodríguez assay + Paillard assay	65.4
BRD shell analysis + Microbiological characterization + Rodríguez assay + Paillard assay	69.2

the target DNA, DNA sequencing of PCR positives prior to routine use of the primers is recommended (Cunningham 2002). In the current study, PCR products obtained using the Paillard et al. (2006) primers were sequenced and found to be consistent with reference *V. tapetis* sequences from the European Molecular Biology Laboratory (EMBL) database, thereby suggesting that the nine PCR positives, detected by this assay only, reflected real *V. tapetis* DNA. In general, however, a PCR positive result alone is not considered enough to confirm the presence of a pathogen, and should be supported by other diagnostic methods before a confirmatory diagnosis is obtained (Walker & Subasinghe 2000).

Two individuals, who displayed brown conchiolin deposits, went undetected for *V. tapetis* by both PCR assays. It is possible that the conchiolin was deposited in response to an agent other than *V. tapetis*, because conchiolin deposition unassociated with *V. tapetis* has been observed in other bivalves (Sindermann 1990, Paillard 2004); this seems unlikely, however, as the pathogen was detected in other individuals within the current sample. Alternatively, the deposits may have persisted in these animals from the conchiolin deposit stage (developmental) of the disease, but the causative agent may have been reduced to nondetectable levels during the recovery stage: the shell repair process is associated with a decrease in *V. tapetis* burden (Allam et al. 1996). The PCR-negative results could also be explained by the pathogen being localized predominantly in tissues other than those targeted for DNA extraction and PCR. In this case, PCR analysis was carried out on the EPF of individuals, but *V. tapetis* is also known to heavily colonize the periostracal lamina and the mantle surface (Paillard & Maes 1995a, 1995b; Allam et al. 1996, Paillard 2004). It is possible that in these two individuals, the pathogen was localized predominantly in the periostracal lamina or on the mantle surface, neither of which was analyzed by PCR and therefore went undetected by both assays.

Isolation and characterization of *V. tapetis* by bacteriological methods produced detection levels of 36.5%, the second highest detection level of the single techniques. However, the lack of sensitivity of the technique is highlighted by the fact that a significant proportion of its negatives (17 of 33) were detected as positive by one or more of the other techniques. Problems associated with the microbiological isolation and characterization of *V. tapetis* have been described in previous studies. In southwestern Spain, microbiological methods failed to detect *V. tapetis* in cultured Manila clams displaying disease signs identical to those of BRD (Castro et al. 1992, 1995; 1997). In bacteriological analyses of the clams' conchiolin deposits, none of the isolates were phenotypically typed as *V. tapetis* (Castro et al. 1997). The pathogen was subsequently detected by an indirect immunofluorescence technique and the authors suggested that lower pathogen levels, detected in *V. philippinarum* from this region in comparison with BRD-affected clams from other regions, were the reason that standard microbiological methods failed to isolate the pathogen (Castro et al. 1997). Similarly, Paillard (2004) stated that isolation of *V. tapetis* might not provide a clear diagnosis because the bacterium grows slowly and is generally nonpredominant within the total heterotrophic microflora. Immunological techniques for the detection of bacterial pathogens in other species have previously been found to be more sensitive than classical microbiological tests (Bernoth 1991, Lee & Gordon 1987).

Nevertheless, isolation of the causative agent is often essential in diseases of a bacterial etiology. Microbiological detection proved to be the most time-consuming and labor-intensive of the

techniques in the present study. In epidemiological studies, involving large sample sizes of clams, the time taken and labor required for completion of microbiological tests would render this technique unsuitable. There are commercial kits available, such as the API 20E (BioMérieux, France), for the rapid identification of *Vibrios*, but whereas previous studies have found them to be effective for *V. tapetis* identification (Allam et al. 2000b, Jensen et al. 2003), the authors of the current study found them unreliable (unpubl. data).

BRD diagnosis has traditionally been achieved by analysis of the brown conchiolin deposit on the shell valves (Paillard & Maes 1994, Allam et al. 1996, Figueras et al. 1996, Paillard et al. 1997, Novoa et al. 1998, Allam et al. 2000a, 2000b; 2001, Reid et al. 2003b, Paillard et al. 2004, Soudant et al. 2004). Whereas it proved to be the least sensitive technique in the current study, failing to detect many positives detected by the other techniques, it is essential for BRD diagnosis: it is the only technique of those used in this study, which detected the actual disease, as opposed to the aetiological agent, which is detected by PCR detection and microbiological isolation. Shell analysis is also useful for classification of BRD into its stages, and thus its assessment of how chronic the infection is and the state of recovery in an individual (Paillard & Maes 1994).

In the current sample, just four animals were BRD-positive as detected by shell analysis, yet up to 32 animals were positive for *V. tapetis* (by a combination of the other techniques). This suggests that there was far more *V. tapetis* than BRD in the sample, and that this may also be true of *V. tapetis* and BRD in the environment. The bacterium has already been detected in other clam species (e.g., *R. decussatus* and *Venerupis aurea*; Maes & Paillard 1992, Novoa et al. 1998) and in other animals such as the cockle, *Cerastoderma edule* (Maes & Paillard 1992), the wrasse *Symphodus melops* (Jensen et al. 2003) and the halibut, *Hippoglossus hippoglossus* (Reid et al. 2003a), suggesting it is widespread in the environment in general. Like most *Vibrios*, it is likely to be an opportunistic pathogen, which does not always generate disease: *V. philippinarum* has been shown to harbor *V. tapetis* without experiencing BRD and associated mortalities (unpubl. data; Castro et al. 1997). Consequently, the detection of *V. tapetis* alone is not sufficient for a clear diagnosis of BRD, because it is not indicative of disease. The observation of clinical disease signs on the hosts' shells, even if only in small numbers as in the current sample, is necessary. Shell valve analysis is thus an essential tool in BRD diagnosis. An exception perhaps arises in cases of acute disease, in which the clam dies prior to manifestation of brown ring signs: this has occurred after injection of *V. tapetis* into the clam's extrapallial space or adductor muscle (Allam et al. 2002). There is no known documented evidence of such an occurrence in the wild.

The major drawback of BRD diagnosis by shell analysis alone is that the brown ring symptom is neither exclusive to BRD, nor exclusive to clams. Essentially, the brown conchiolin deposit is a defense mechanism and has been observed in many bivalves undergoing infection such as oysters (Perkins 1996, Cuif & Dauphin 1996) and abalone (Sherperd & Huchette 1997). See review by Paillard (2004). Parasites such as fungi, annelids and trematodes can disturb the extrapallial area by boring into or irritating the mantle epithelium (Sindermann 1990, Paillard et al. 1994). As such, brown rings on shell valves of clams are not exclusively caused by infection by *V. tapetis*. For this reason, a diagnosis of BRD based on shell analysis alone is insufficient; evidence of the aetiological agent is also required.

A combination of diagnostic techniques is therefore necessary for an accurate BRD diagnosis. The results here demonstrated the effectiveness of various combinations. The more techniques used in a particular combination did not necessarily lead to a higher detection rate, although the use of all four methods produced the highest detection levels. There was significant variability in detection rates when various combinations of two techniques were used, from 21.2% to 61.5% detection in the sample; each combination of two tests involving the Paillard assay produced detection levels above 50%, whereas those not using the assay produced detection levels below 50%. It would appear therefore that for sensitive detection, any combination of two techniques should involve the assay of Paillard et al. (2006). There was less variability in detection levels when combinations of three techniques were used: 51.9% to 65.4%. Diagnosis by a combination of three techniques provided detection levels not dissimilar to those produced from a combination of all techniques (i.e., 69.2%), indicating that it is unnecessary to use all four diagnostic methods in an analysis, unless the objective is to ensure, as far as possible, that clams are BRD/*V. tapetis*-negative.

In BRD management, the diagnostic methods, or combinations thereof, applied in an analysis of clams for BRD/*V. tapetis* will depend on a number of factors, specifically, the information required from the analysis; the number of individual clams in the sample to be analyzed; the time available and the financial resources available. A clam sample should first be assessed for overt BRD signs on the shell and then for the presence of the aetiological agent. The testing of clam seed for *V. tapetis*/BRD in the hatchery prior to purchase would best be accomplished by analyses for detection of the pathogen, as clinical BRD signs cannot be observed in juveniles under 2 mm (and in larvae) (Paillard et al. 2006).

In conclusion, the analyses of diagnostic techniques carried out in the current study demonstrate that none of the four techniques

was sufficient on its own for an accurate diagnosis of BRD. BRD shell analysis was an essential technique and is recommended as the first technique in the analysis of a clam sample for BRD, followed by confirmation, either by PCR or microbiology, that the brown deposits are caused by *V. tapetis*. The combination of BRD shell analysis and PCR detection according to Paillard et al. (2006) was the most sensitive and rapid combination in this study. In instances where isolation of the aetiological agent is required and time is not a limiting factor, BRD shell analysis in conjunction with microbiological techniques is recommended. PCR detection is valuable if sensitivity for detection of lower pathogen levels is required. A comparison of the cost-efficiency of each method favored BRD shell analysis, followed in increasing cost by bacteriological isolation and characterization, and finally, either of the two sets of primers.

The results here were based on a single sample, and the sample size of 52 individuals is less than the 60 recommended by Simon & Schill (1984) for detection of an infection present at 5% prevalence in a population of 1×10^6 . Additionally, the sample represents a single month, and therefore does not consider seasonal variation in BRD and *V. tapetis* prevalence. Further studies, which would encompass seasonal sampling, are required for validation of the detection efficiency of each technique. However, the results here provide a basis for deciding on diagnostic and detection techniques of choice for BRD and *V. tapetis* in different situations.

ACKNOWLEDGMENTS

The authors thank Dr. Jesús L. Romalde and Dr. Christine Paillard for training in the use of PCR for *V. tapetis* screening and Dr. Jamie Coughlan and Dr. Eileen Dillane for sequencing work. This project was carried out with the support of the Marine Institute and the Marine RTDI Measure, Productive Sector Operational Programme, National Development Plan 2000–2006.

FLUOROMETRIC MEASUREMENT OF OXIDATIVE BURST IN LOBSTER HEMOCYTES AND INHIBITING EFFECT OF PATHOGENIC BACTERIA AND HYPOXIA

BRANDON MOSS AND BASSEM ALLAM*

Marine Sciences Research Center, Stony Brook University, Stony Brook, New York 11794

ABSTRACT The stimulation of hemocytes during phagocytosis leads to the generation of a series of oxygen radicals known as reactive oxygen species (ROS). Among these, hydrogen peroxide plays an important microbicidal role by directly killing microorganisms or by serving as an intermediate for other antimicrobial radicals. In this study, we adapted a technique using 2',7'-dichlorofluorescein-diacetate (DCFH-DA) to measure H_2O_2 production in lobster hemocytes. After oxidation by hydrogen peroxide, this molecule produces a fluorescent product that can be easily detected. The respiratory burst was successfully activated in lobster hemocytes by the addition of zymosan particles, but not with phorbol myristate acetate. After optimization, we used the technique to investigate the effect of different bacterial strains, including lobster pathogens, on the oxidative burst. Results demonstrate that *Aureococcus viridans*, a bacterial pathogen that is able to survive phagocytosis by lobster hemocytes, quenches ROS production. The comparison of ROS production in lobsters collected from field sites submitted to different levels of dissolved oxygen suggests that this technique provides a good indicator of lobster physiological status and immunocompetency.

KEY WORDS: lobster, *Homarus americanus*, oxygen, *in vitro*, dichlorofluorescein diacetate, ROS

INTRODUCTION

The American lobster, *Homarus americanus*, is one of the most commercially important species in the Northeastern United States and Canada. This species is subject to different infections, including those caused by bacterial agents such as the Gram-positive *Aerococcus viridans* (Stewart et al. 1969, Battison et al. 2003) and the Gram-negative *Vibrio fluvialis* (Tall et al. 2003), as well as those related to protozoan parasites such as *Paramoeba* (Mullen et al. 2004) and the ciliate *Anophryoides hemophila* (Cawthorn 1997, Athanassopoulou et al. 2004). Against these pathogens, lobsters have a set of cellular and humoral defense factors. In common with other crustaceans, host defense in lobsters is nonspecific, based on activities of circulating hemocytes (Bauchau 1981, Paterson & Stewart 1974, Paterson et al. 1976, Cornick & Stewart 1978, Battison et al. 2003). In these animals, hemocytes defense functions include coagulation, phagocytosis, encapsulation and wound repair (Bauchau 1981, Johansson & Söderhäll 1989, Bachère et al. 1995) and synthesis and secretion of humoral defense factors (Destoumieux et al. 2000, Bachère et al. 2004).

The stimulation of hemocytes during phagocytosis leads not only to release of lysosomal enzymes, but also to superoxide radical (O_2^-) generation catalyzed by NADPH oxidase associated with the cytoplasmic membrane. Superoxide radical is metabolized to hydrogen peroxide (H_2O_2) by superoxide dismutase (SOD), and the resulting peroxide is further converted to hypochlorite (OCI^-) by myeloperoxidase (MPO). Hydrogen peroxide, superoxide radical and hypochlorous acid exhibit direct antimicrobial activity and are widely called reactive oxygen species (ROS) or intermediates (ROI). This phenomenon, known as respiratory burst, plays an important microbicidal role (Anderson 1996). Prior studies reported that ROS production is inhibited in shellfish experimentally submitted to environmental (pollutants, hypoxia) and pathogenic (bacterial) stresses (Anderson 1994, Anderson et al. 1997, Lambert & Nicolas 1998, Le Moullac et al. 1998, Cheng et al. 2002, Lambert et al. 2001).

Because of their importance in the defense process, various tools have been developed to measure ROS production in verte-

brates, including microscopy, luminescence methods and flow cytometry techniques. In their recent paper, Anderson & Beaven (2005) described a chemoluminescence method measuring the oxidative burst in lobsters after activation with Phorbol myristate acetate (PMA). An appealing alternative to this technique is a method using 2',7'-dichlorofluorescein-diacetate (DCFH-DA), initially developed in human phagocytic cells (Rosenkranz et al. 1992). After oxidation by ROS (particularly H_2O_2), this molecule produces a fluorescent product that can be easily detected using fluorescence microscopy, or measured using appropriate fluorometers (plate readers, flow cytometers).

There were several goals for this study. First, a simple fluorometric technique allowing detection and quantification of ROS production in lobster hemocytes was devised and optimized. This technique was then used to investigate the effect of pathogenic (bacterial) challenge on ROS production. Finally, as field evaluation of the optimized method, this study examined ROS production in lobsters collected from three different locations in Long Island Sound known to be submitted to different levels of dissolved oxygen.

MATERIALS AND METHODS

Lobsters

Lobsters (1.25–1.50 lb.) used for technique-setup experiments were obtained from a commercial source located in Port Jefferson, New York. Lobsters used to investigate the effect of bacteria on ROS production were collected from traps deployed north of Oak Neck, Long Island Sound (Fig. 1). Animals were maintained in 200-L tanks (3 lobsters per tank), filled with aerated recirculating seawater containing artificial shelters made of PVC pipes. The water, which was maintained at 32 ± 1 ppt and $15 \pm 1^\circ C$, was continuously pumped through a canister filter system containing active biofilter media made from sintered glass (Eheim Ehflubstrat, Aquatic Eco-Systems Inc., Apopka, Florida) and active carbon. Nitrate/nitrite and ammonia levels were monitored, and water changes were made when needed. Lobsters were fed twice a week, using clam meat for a minimum period of 7 days before bleeding and ROS measurement. To investigate ROS production in lobsters exposed to different levels of dissolved oxygen, additional lobsters

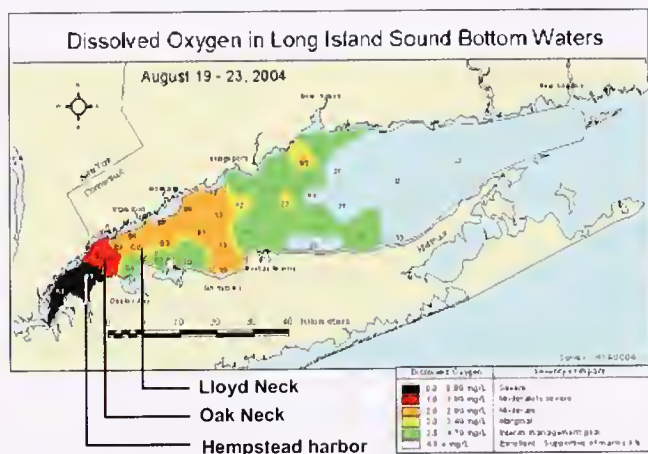

Figure 1. Map showing lobster sampling sites in Long Island Sound and dissolved oxygen in bottom waters during the sampling period (Map generated by CT DEP Long Island Sound Water Quality Monitoring Program, accessible online at: <http://www.dep.state.ct.us/wtr/lis/monitoring/summer2004.htm>)

were collected from different locations within Long Island Sound (Fig. 1): 12 lobsters were collected from traps located north of Hempstead Harbor, 15 from traps located north of Oak Neck, and 15 from traps located north of Lloyd Neck. These lobsters were maintained in seawater tanks onboard of the fishing vessel until transferred to the laboratory for immediate hemolymph sampling and processing.

Chemicals and Buffers

Crustacean anticoagulant (CAC, 0.45 M NaCl, 0.1 M glucose, 0.03 M trisodium citrate, 0.026 M citric acid, and 0.01 M EDTA, pH 4.6) and marine crustacean saline (MCS, 0.58 M NaCl, 0.013 M KCl, 0.013 M CaCl₂, 0.026 M MgCl₂, 0.00054 M N₂HPO₄, and 0.05 M Tris-HCL buffer, pH 7.6) solutions were prepared according to Smith and Söderhäll (1983). Dichlorofluorescein diacetate (DCFH-DA, Sigma) was dissolved in DMSO to obtain 100 mM stock solution (aliquoted and stored at -20°C). Work solutions of DCFH-DA were produced by diluting aliquots in filtered (0.22 µm) autoclaved seawater (FASW) at different concentrations as described later. Phorbol myristate acetate (PMA, Sigma) stock solution was made by dissolving 1 mg PMA in 1 mL dimethyl sulfoxide (DMSO). This solution was divided into 25-µL aliquots and stored at -20°C. Zymosan (Sigma) was directly suspended in FASW (20 mg 1 mL⁻¹), then heated in a boiling water bath for 30 min. The resulting suspension was then washed twice by centrifugation and resuspension in MCS. The particle count was checked microscopically and aliquots were frozen at -20°C.

ROS Measurement

General Design

Hemolymph (0.5 mL) was withdrawn from the ventral sinus by inserting a needle at the base of the last left walking leg. Hemolymph was directly collected in a 3-mL syringe containing 2.5 mL CAC to prevent blood clotting. Diluted hemolymph was then centrifuged (300g, 4°C, 10 min). The supernatant was discarded, and the cells were resuspended in 1 mL MCS. An aliquot (100 µL) of resuspended hemocytes was added with formalin (2% final concentration) and used for hemocyte count. Remaining

hemocytes were added to a 96-well black microplate (100 µL per well, in 3–4 replicates depending on experiments) and were supplemented with DCFH-DA. An initial reading of the fluorescence (485 nm excitation and 535 nm emission) was then performed to measure the native (prior to activation) ROS production in hemocytes using a Wallace 1420 fluorometric plate reader. After the first reading, hemocytes were added with targeted activator (PMA or zymosan, see below), then additional fluorescence readings were recorded after 5 and 30 min of incubation in the dark.

Activation With PMA Versus Zymosan

Hemocytes resuspended in MCS were added to a 96-well microplate as follows: for each lobster ($n = 3$ lobsters), nine replicate wells containing 100 µL per well were performed: 3 wells received 100 µL MCS containing 2 µL PMA stock solution (10 µg mL⁻¹ final concentration), another three received 100 µL Zymosan suspension made in MCS (1:50 hemocyte:zymosan ratio), and the last three received MCS as a control. Then 2 µL DCFH-DA stock solution were added to each well (final DCFH-DA concentration = 1 mM). Readings were taken using the Wallace fluorometric plate reader at 5, 20, 60, 90 and 120 min postactivation.

Determination of Optimal DCFH-DA Concentration

Hemocytes were processed in the same way as above. For each lobster ($n = 3$), four replicate wells were performed, and each of these wells received a different concentration of DCFH-DA. The different concentrations tested were: 0.1, 0.5, 1, and 2 mM DCFH-DA. The Wallace plate reader was set up to take automatic readings at 5-min intervals for a total of 90 min after activation with zymosan (1:50 hemocyte:zymosan ratio).

Effect of Bacterial Challenge on ROS Production

The significance of pathogenic stress was investigated by studying the effect of *in vitro* challenge with bacterial compounds on ROS production in lobster hemocytes. Four bacterial strains were investigated: *Aerococcus viridans* var. *homari* (Robohm et al. 2005) and *Vibrio fluvialis* (Tall et al. 2003), both known to be pathogenic to lobsters, *Listonella anguillarum* (strain 775, Crosa et al. 1977), a pathogen to several marine organisms including fish and shellfish, and *Escherichia coli*, which is not known to cause disease in marine organisms (here used as control). Bacteria were cultured in sterile marine broth (Difco 2216) at room temperature on a shaker table for about 24 h (exponential phase of growth). After spectrophotometrically estimating bacterial counts, bacterial cells were collected by centrifugation (3,000g, 15 min, 4°C), resuspended in MCS and used immediately for challenge experiments. Bacterial supernatants were filtered (0.22 µm) and saved (-20°C) for use in subsequent experiments.

The first experiment investigated the effect of challenge of hemocytes with bacterial cells on ROS production using additional lobsters collected from Lloyd Neck. For each lobster (9 total), 12 wells received 100 µL of hemocytes resuspended in MCS, supplemented with DCFH-DA at a final concentration of 0.5 mM. After an initial reading to measure native ROS activity, duplicate wells received 20 µL of one of the following suspensions (at a ratio of 1:50 hemocytes:test particles, e.g., cfu or zymosan): *A. viridans*, *V. fluvialis*, *L. anguillarum*, *E. coli*, zymosan, and two wells received 20 µL MCS as a control. After a 30-min incubation in the dark, a second reading was taken, then 10 µL zymosan were added to each well and two more readings were taken after 5 and 30 min addi-

tional incubation. Aliquots of hemolymph samples were diluted in CAC, fixed with formalin (1.9% final concentration) and used for hemocyte counts with a hemocytometer. ROS production was normalized to hemocyte counts.

The second experiment investigated the effect of bacterial supernatants on ROS production by hemocytes. For each lobster (9 total), 12 replicated wells received 100 μ L of hemocytes resuspended in MCS. Duplicate wells were added with 100 μ L of bacterial (*A. viridans*, *V. fluvialis*, *L. anguillarum*, *E. coli*) supernatants. The volume of supernatant added per hemocyte was estimated to be equivalent to the volume of culture medium containing 50 cfu (supernatant-cfu equivalent). Two other wells received 100 μ L MCS as a control and two additional wells received 100 μ L sterile culture media as a second control. After 1-h incubation, DCFH-DA was added to each well at a final concentration of 0.5 mM and baseline fluorescence reading was taken. Then 10 μ L zymosan was added to each well and readings were taken 5 and 30 min after incubation in the dark. ROS production was normalized to hemocyte counts as described above.

Effect of Hypoxia on ROS Production

This experiment investigated ROS production in lobsters collected from areas on Long Island Sound known to be submitted to different levels of dissolved oxygen as determined by the Connecticut Department of Environmental Protection (CT DEP) Long Island Sound Water Quality Monitoring Program (Fig. 1). The biweekly summer survey generates hypoxia maps based on the monitoring of different stations across the sound using a CTD recorder. Lobsters were transferred to the laboratory and hemocytes were withdrawn as previously described. For each lobster, four wells received 100 μ L of hemocytes resuspended in MCS, supplemented with DCFH-DA at a final concentration of 0.5 mM. After an initial fluorometric reading to measure native activity, 10- μ L Zymosan suspension was added to each well to activate ROS production (about 1:50 hemocyte:zymosan ratio). Two additional readings were then made 5 and 30 min after incubation in the dark. ROS production was normalized to hemocyte counts as described for the bacterial challenge experiments.

Statistics

Average fluorescence signals were calculated for all replicated wells before being processed for statistical analyses. All data were analyzed using the Statgraphics statistical software. Statistical tests were a one-way general linear model analysis of variance (ANOVA) or repeated measure ANOVA followed by a Fisher's LSD posthoc test, as appropriate. Because raw data were not always normally-distributed, a Log₁₀-transformation was made on data before running statistical testing. Differences were considered significant at $\alpha = 0.05$.

RESULTS

Activation of Hemocytes for ROS Production

The addition of 1 mM dichlorofluorescein diacetate (DCFH-DA) to hemocytes induced the production of baseline fluorescence that increased with incubation time, up to 120 min after incubation (maximal incubation period assayed in this study, Fig. 2). Because the fluorescence signal is an indicator of hydrogen peroxide production, these results suggest that ROS are produced in untreated hemocytes. Hydrogen peroxide production was significantly

Figure 2. Oxidative burst in hemocytes activated with phorbol myristate acetate (PMA) or zymosan (ZYM). Control hemocytes were incubated with saline (MCS). Fluorescence signals were significantly higher (*) in hemocytes added with zymosan when compared with the 2 other treatments (Fisher's LSD posthoc test, $P < 0.05$, $n = 3$).

stimulated by the addition of zymosan A ($P < 0.001$, repeated measure ANOVA) within 20 min after activation, but was not modified by the addition of PMA, when compared with untreated hemocytes (added with saline). These trends were not modified over the 2-h duration of the experiment.

Determination of Optimal DCFH-DA Concentration

Fluorescence signals intensified with the increase of DCFH-DA concentration from 0.1–0.5 mM (Fig. 3). Further increase in concentration to 1 or 2 mM did not enhance the intensity or modify the kinetics of H₂O₂ production. Based on these results, a concentration of 0.5 mM was used in all subsequent experiments.

Effect of Bacterial Cells on the Oxidative Burst

Thirty minutes after the addition of bacterial cells to hemocytes, ROS production significantly increased in wells incu-

Figure 3. Oxidative burst in hemocytes added with different concentrations of dichlorofluorescein diacetate (DCFH-DA) and activated with zymosan. *: significant differences between hemocytes added with 0.1 mM and all other treatments appeared 25 min after incubation and continued until the end of the experiment (Fisher's LSD posthoc test, $P < 0.05$, $n = 3$).

Figure 4. Effect of bacterial cells on reactive oxygen species production in lobster hemocytes. Zimosan was added to all wells after the second fluorescence reading. MCS: saline, ZYM, zimosan, LA: *Listonella anguillarum*, EC: *Escherichia coli*, AV: *Aerococcus viridans*, VF: *Vibrio fluvialis*. For each time interval, letters (a and b) represent significant differences among different treatments (Fisher's LSD post hoc test, $P < 0.05$, $n = 9$). *: significant increase when compared with the prior sampling point (Student *t*-test, $P < 0.05$).

bated with *E. coli*, when compared with control hemocytes added with saline (Fig. 4). The other bacterial species caused only a slight increase in fluorescence signals that did not significantly differ from control hemocytes. Among this group, *V. fluvialis* caused the highest signals, followed by *L. anguillarum* and finally by *A. viridans*. The subsequent activation of hemocytes with zimosan did not significantly change the trends observed in hemocytes preincubated with bacteria. The major changes were observed in hemocytes initially used as controls (added with saline), in which the addition of zimosan produced the strongest signals (Fig. 4). A second addition of zimosan to hemocytes did not noticeably increase ROS production.

Effect of Bacterial Extracellular Products on the Oxidative Burst

Pre-incubation of hemocytes with bacterial extracellular products (ECP) did not affect native hydrogen peroxide production in

Figure 5. Effect of bacterial extracellular products (ECP) on reactive oxygen species production in lobster hemocytes. See legend of Figure 4 for abbreviations. For each time interval, letters (a, b and c) represent significant differences among different treatments (Fisher's LSD posthoc test, $P < 0.05$, $n = 9$).

Figure 6. Reactive oxygen species production in lobsters collected from three different locations in Long Island Sound (see Figure 1 for more details). Each data point represents 12 (Hempstead Harbor) or 15 (Oak Neck Harbor and Lloyd Neck) lobsters. Letters (a and b) represent significant differences among samples (Fisher's LSD posthoc test, $P < 0.05$).

inactivated hemocytes. However, hemocytes preincubated with ECP from *L. anguillarum* were unable to express oxidative bursts in response to zimosan activation (Fig. 5). Preincubation of hemocytes with ECP produced by the other bacterial species slightly increased ROS production when compared with saline control. However, ROS signals in these samples were not significantly different from those of control hemocytes incubated in sterile bacterial culture media.

Effect of Hypoxia on ROS Production

Native hydrogen peroxide production in inactivated hemocytes was significantly higher in lobsters collected from the most western field site (Hempstead Harbor), when compared with lobsters from Oak Neck and Lloyd Neck (Fig. 6). This trend is inverted after activation. For instance, thirty minutes after the addition of zimosan, oxidative burst was significantly higher in lobsters collected from the most eastern site when compared with the two other locations. Hemocyte counts were not significantly different among the different field sites and ranged from 1.9×10^6 to 4.8×10^6 hemocytes mL^{-1} .

DISCUSSION

Oxidative burst by blood cells is a major antimicrobial mechanism in vertebrates and invertebrates. This oxidative process starts when stimulation of macrophages leads to increased consumption of oxygen, the reduction of which, catalyzed by a membrane-bound NADPH oxidase, initiates the cascade and production of several reactive oxygen species. This study demonstrates that the optimized fluorometric technique represents a valuable method for the measurement of oxidative burst by lobster hemocytes, and provides a viable means of evaluating the effects of pathological and environmental stresses on lobster immunity. Our results show that dichlorofluorescein-diacetate (DCFH-DA) is cleaved into fluorescent dichlorofluorescein in hemocytes incubated in saline at a significantly lower rate than in hemocytes added with zimosan. Higher cleavage rate clearly indicates a higher production of hydrogen peroxide through activation of the ROS cascade (Rosen-

kranz et al. 1992). The fluorescent signal increased with incubation time, including that in control hemocytes, as a result of accumulation of dichlorofluorescein in cells. Fluorescent signals observed in control hemocytes correspond to spontaneous H_2O_2 production, which may reveal a normal physiological cell activity. Alternatively, such production can be related to an activation of hemocytes during the isolation procedure, or when the hemocytes adhere to the plastic as observed, for instance, for bivalve (Pipe 1992) or hypothesized for crustacean (Bachère et al. 1995) hemocytes. Incubation of hemocytes with phorbol myristate acetate (PMA, $10 \mu\text{g mL}^{-1}$) did not induce any increase in hydrogen peroxide production. This is in agreement with several studies that found that PMA is not as efficient in inducing ROS production as zymosan in crustaceans (Song & Hsieh 1994, Bachère et al. 1995, Muñoz et al. 2000) and in mollusks (Ordas et al. 2000, Austin & Paynter 1995, Torreilles et al. 1997), but in disagreement with a prior report that showed higher ROS production in lobster (*H. americanus*) hemocytes activated with PMA, when compared with cells added with zymosan (Anderson & Beaven 2005). This apparent contradiction could be explained by the fact that Anderson & Beaven measured the production of a subsequent reactive intermediate in the cascade, namely $HOCl$, using a chemiluminescence detection method. The fact that the hemocyte:zymosan ratio used here (1:50) is significantly higher than ratios used by those authors (1:2–1:25) may provide another explanation of the differences observed between the two studies, because our preliminary results showed an increase in hydrogen peroxide production with the increase of hemocyte:zymosan ratio up to 1:50 (data not shown).

The possible role of lobster hemocyte ROS in the elimination of pathogenic microorganisms was investigated by studying the effect of selected bacteria on ROS production *in vitro*. Our results demonstrated that *E. coli* and *V. fluvialis* cells caused an increase in ROS production, but differences compared with the control were only significant in the case of *E. coli*. Although a prior report also demonstrated that *E. coli* cells induced the highest ROS response in shrimp hemocytes when compared with shrimp bacterial pathogens (Muñoz et al. 2000), the biological significance of these results is not clear, because *E. coli* is not significantly present in natural lobster habitat. It seems, however, that some bacterial pathogens have developed strategies to avoid the trigger of ROS production by hemocytes. For instance, Muñoz et al. (2000) demonstrated that a pathogenic strain of *Vibrio harveyi* did not induce ROS production when added to shrimp hemocytes, whereas the addition of a strain of *V. alginolyticus* used as probiotic in shrimp aquaculture did enhance ROS production. Similarly, our study revealed that *Aerococcus viridans*, a pathogen that is able to survive phagocytosis by lobster hemocytes (Stewart 1975), does not elicit ROS production. Similarly, the universal pathogen *L. anguillarum* did not induce the production of ROS. More importantly, ROS production in these two samples was not increased after the addition of zymosan, suggesting an active neutralization of the oxidative metabolism by *A. viridans* and *L. anguillarum*. Although bacterial cells from both strains have similar effects, the mechanisms underlying their ROS inhibition might be different. It has already been demonstrated that the survival in hosts' cells of pathogenic bacteria and fungi is often linked to the ability of these microorganisms to quench ROS through the production of catalases/peroxidases, which are thus considered virulence factors (Day et al. 2000, Lefebvre & Valvano 2001, Pongpom et al. 2005). It is thus possible that *A. viridans* quenches ROS production in

lobster hemocytes as a mean to colonize and survive within host's cells. The antioxidant enzyme catalase is not present in this bacterial species, however, suggesting that such quenching might be performed through other processes. The effect of *L. anguillarum* on ROS production is more pronounced when bacterial extracellular products (ECP) are used. *L. anguillarum*, which possesses catalase activity, may suppress fluorescence signals by altering H_2O_2 production as suggested by Bramble and Anderson (1997). Alternatively, the same strain of this universal pathogen has demonstrated wide cytotoxic effects on hemocytes from different bivalve species under similar experimental conditions (Allam & Ford 2006). The viability of hemocytes was not specifically monitored in the present work, but anecdotal observations suggested increased mortality only in hemocytes incubated with *L. anguillarum* (data not shown). The effect of *L. anguillarum* observed here might simply be a result of hemocyte killing by bacterial cells and ECP, because dead hemocytes could not participate in ROS production.

The comparison of ROS production in lobsters collected from field sites submitted to different environmental conditions suggests that this technique represents a good indicator of lobster physiological status and immunocompetency. The major environmental condition that varies among experimental sites was the level of dissolved oxygen, which ranged from levels below 1 mg L^{-1} in Hempstead harbor to about 3 mg L^{-1} in Lloyd Neck. Native hydrogen peroxide production was 3 times higher in hemocytes from lobsters collected in the former, when compared with those harvested from the latter. High native (base) ROS production may reveal stressful or injurious situations caused by *in situ* factors. These findings suggest that lobsters from Hempstead harbor had been submitted to oxidative stress, which may have been caused by low oxygen availability in the environment (Storey 1996, Pan et al. 2003). Animals typically respond to hypoxia by reducing metabolic rate (Perez-Rostro et al. 2004), but side effects of hypoxia include the formation of excess free oxygen radicals (Yu 1994, Pan et al. 2003), causing severe alterations in cellular activities. Although these microbiocidal agents are typically generated in the phagocytic vacuoles, an important quantity crosses into the extravacuolar environment and may cause damage to cells (Warner 1994, Thompson et al. 1995). ROS also damage cytoskeletal proteins, leading to a probable loss in defense function, because hemocyte adhesion, motility, endocytic ability and the capacity to phagocytose foreign particles all depend on the cytoskeleton (Bellomo & Mirabelli 1992). The prevention of such damages is normally made through different defense strategies, which involve the use of small antioxidant molecules (ascorbate, glutathione, carotenoid pigments) that can directly neutralize oxidative radicals, or rely on a variety of enzymes that metabolize ROS (superoxide dismutase, catalase, glutathione peroxidase) (Warner 1994). In any case, subsequent stimulation with a specific trigger of the respiratory burst could be impaired, ineffective or unreliable. For instance, hemocytes from hypoxic areas (Hempstead and Oak Neck) did not respond to zymosan activation as efficiently as those collected from Lloyd Neck. Similarly, Le Moullac et al. (1998) demonstrated a decrease in ROS production, measured by the nitroblue tetrazolium method, in shrimps submitted to hypoxia. In our study, the lowering of ROS production may hamper the lobster's ability to mount an effective defense against invading microorganisms in areas affected with hypoxia, thus amplifying stress to such animals and leading to mass mortality events such as those that have been observed in western Long Island Sound.

In conclusion, this paper describes a simple technique to measure oxidative burst in lobster hemocytes. The technique was used to demonstrate a deleterious effect of some bacterial pathogens on ROS production in lobster. Additionally, the technique seems promising for field monitoring of lobster immunocompetency. Our results suggest that pathogen and environmental stresses may combine and act together to create potentially disastrous conditions for lobsters.

ACKNOWLEDGMENTS

The authors thank the New York State Department of Environmental Conservation for help with lobster sampling and fund-

ing and the Connecticut Department of Environmental Protection (Long Island Sound Water Quality Monitoring Program) for allowing the use of the hypoxia map. The authors are indebted to Dr. R. Robohm for providing two bacterial strains and to Mrs. D. Tsang for editorially-reviewing this manuscript. The authors also thank Dr. A. McElroy for allowing access to her lab and Dr. R. S. Anderson (Chesapeake Biological Laboratory) for sharing with us an early draft of his paper on ROS in lobsters. This paper is partially a product of a summer research internship performed by B. M. Field work was done with the assistance of Ms. A. Tribble and Dr. A. Dove.

AN IMPROVED AND RAPID BIOCHEMICAL IDENTIFICATION OF INDIGENOUS AEROBIC CULTURABLE BACTERIA ASSOCIATED WITH GALICIAN OYSTER PRODUCTION

ROSA FARTO,¹* JOSÉ ANTONIO GUISANDE,¹ SUSANA P. ARMADA,¹ SUSANA PRADO,² AND TERESA P. NIETO¹

¹Dpto. de Biología Funcional y Ciencias de la Salud, Facultad de Biología, Universidad de Vigo, Spain; ²Dpto. de Microbiología y Parasitología, Universidad de Santiago de Compostela, Spain

ABSTRACT An improved and rapid biochemical identification of the culturable aerobic bacteria species associated with Galician oyster production was performed by the combination of numerical taxonomy and sequencing of 16S rRNA gene. The 16S rRNA sequences of 23 representative bacterial isolates from different growing stages of *Ostrea edulis*, surrounding water, and phytoplankton were compared with related sequences from the EMBL database. These results were used to identify the phenetic clusters obtained by numerical taxonomy using the *S*_J/UPGMA with a similarity level of 74%. The combination of the two techniques was a useful tool for identifying 40 out of 75 representative aerobic Gram negative isolates comprising the bacterial community studied and for improving the phenotypical description of each identified species. It was mostly facultative psychrophilic γ -*Proteobacteria* showing a great diversity. No specificity of bacteria, according to the geographical area studied was found. Almost all of the identified species were associated, for the first time, with different growing stages of oyster. Some could have a probiotic effect (*Roseobacter gallaeciensis*, *Shewanella schlegeliana*) or could be a potential risk for oyster cultures (*Pseudoalteromonas piscicida*, *Pseudomonas anguilliseptica*) or for humans by consumption (*Acinetobacter johnsonii*, *Pseudoalteromonas tetraodonis*).

KEY WORDS: oyster, culturable aerobic bacteria, 16S rRNA gene, rapid identification

INTRODUCTION

The main culture of bivalve mollusc volume in Europe is concentrated in Galicia. Maintaining cultures with a high density increases the risks and consequences of infectious outbreaks. The study of natural culturable microbiota is essential for improving the industrial culture production, because it is the first step for designing a rapid presumptive guide for separating environmental and potentially pathogenic bacteria species. In a previous paper, we reported the phenotypical analyses of culturable aerobic bacteria associated with the Galician oyster (*Ostrea edulis*) cultures (Guisande et al. 2004). The samples were obtained monthly from oyster culture systems located on the Galician coast at: Bueu, Couso, Grove, Malpica, Ribadeo, and Vilagarcía de Arousa over 12 consecutive months, as was previously reported. A total of 397 isolates from different stages (seed, larval, and reproductive) of oyster, surrounding water and phytoplankton, selected as being representative of bacterial community, were characterized by numerical taxonomy. Nineteen per cent of isolates (75) were aerobic, gram negative, and using the Jaccard's coefficient at 69% (*S*_J) and the unweighted pair group average method (UPGMA) a great diversity, and a high number of unidentified isolates were obtained.

The aim of our study was to select differential biochemical tests for a rapid identification of isolates after the identification by using the sequencing of 16S rRNA gene technique and numerical taxonomy analysis. A phenotypic description of each identified species will be provided. This study will differentiate between the strains associated with growing oyster stages, with a probiotic role or potentially pathogenic species for oysters or humans.

MATERIALS AND METHODS

Bacterial Strains

A total of 75 aerobic strains were obtained as representatives on a wide study of bacterial community associated with Galician oyster production from different stages (seed, larval, and reproduc-

tive) of oyster (*Ostrea edulis*), surrounding water, and phytoplankton (Guisande et al. 2004). Sampling, processing, and isolation of strains were previously reported by us. Pure cultures of strains were obtained on Marine Agar (Cultimed, Barcelona, Spain) and were stored at -80°C in Nutritive Broth (Cultimed, Barcelona, Spain) with 2% (w/v) NaCl (Pancreac, Barcelona, Spain) and 15% (v/v) of glycerol (Panreac).

Sequencing of 16S rRNA Gene

Sequencing of 23 strains (Table 1) representing all phenotypes and some of unclustered strains of dendrogram previously reported by us (Guisande et al. 2004) was performed according to the method described by Montes et al. (2003) using a 310 Genetic Analyzer (Applied Biosystems, Darmstadt, Germany) automated sequencer. The sequence of the 16S rRNA gene of strains was determined by using four primers (37F, 344F, 344R, and 1096R) and compared with sequences in public databases of GenBank, EMBL and DDBJ with BLAST, version 2.2.6. (Altschul et al. 1997). Multiple alignment of sequences was created by ClustalX, version 1.81 (Higgins & Sharp 1988), which included 1003 positions after removal of ambiguous positions (Hall 2001), using the BioEdit Sequence Alignment Editor, version 5.0.9 (Hall 1999). A phylogenetic tree was constructed by using Molecular Evolutionary Genetics Analysis (MEGA), version 2.1 (Kumar et al. 2001). This was performed using the neighbor-joining method (Saitou & Nei 1987) and Tamura-Nei distance model (Tamura & Nei 1993), with the calculation of cluster stability by bootstrap analysis with 1,000 replicates (Nei & Kumar 2000).

Sequences of Organisms Used for Phylogenetic Trees

All available species of each genus closest to studied strains were selected. In most cases, species type strains (if available) with nearly full-length 16S rRNA sequences were used. This includes members of two phylogenetic groups: Proteobacteria- γ subdivision: *Acinetobacter* (16 species), *Alteromonas* (3 species; it was abbreviated as *Alt.*), *Halomonas* (27 species), *Marinobacter* (7 species), *Mesorhizobium* (5 species), *Pseudomonas* (29 species), *Pseudoalteromonas* (24 species; it was abbreviated as *Pa.*) and

Shewanella (33 species), and Proteobacteria- α subdivision with 3 species of *Roseobacter*.

Nucleotide Sequence Accession Numbers

The partial 16S rRNA sequences of environmental isolates reported in this paper (42, 642, 29.98, 51.98, 73.98, 52.98, 55.98, 82.98, 251, 131, 173, 170, 174, 155, 86, 171, 111, 81, 117, 561, 8.98, 34.98, 38.98) have been deposited in the DDBJ (Mishima, Japan), EMBL (Heidelberg, Germany) and GenBank (Mountain View, USA) nucleotide sequence data bases under accession numbers AY870662 to AY870684, respectively.

Phenotypic Characterization

Bacterial strains and the reference strains were previously characterized by 92 physiological, morphological, and biochemical tests (Guisande et al. 2004). Cultures grown during 24 h at 22°C on Tryptic Soy Agar (TSA, Cultimed) and supplemented up to 2% (w/v) NaCl (Panreac) (TSA 2%) were used as inocula. Data were processed with the NTSYS-pc, version 1.8 (Rohlf 1994). A similarity matrix was calculated using the S_j at 74%. Phenotypes were clustered using the UPGMA method and were defined with the earlier mentioned percentage. The correlation between the dendrogram and the similarity matrix (cophenetic correlation) was determined using the cophenetic correlation coefficient (r). The reproducibility of the tests was evaluated by analyzing 10% of strains in duplicate, as suggested by Sneath and Johnson (1972).

The reference strains included in the numerical taxonomy study

were: *Achromobacter denitrificans* CECT (Colección Española de Cultivos Tipo, Valencia, Spain) 449^T, *Agrobacterium ferrugineum* CECT 4356^T, *Halomonas aquamarina* CECT 5000^T, *Marinomonas communis* CECT 5003^T, *Marinomonas vaga* CECT 5004^T, *Marinobacter hydrocarbonoclasticus* CECT 5005^T, *Porphyrobacter sanguineus* CECT 4271^T, *Pseudoalteromonas* (abbreviated as *Pa*) *citrea* CECT 575^T, *Pa. espejiana* CECT 5002^T, *Pa. haloplanktis* CECT 4188^T, *Pa. undina* CECT 5006^T, *Pseudomonas fluorescens* CECT 378^T, *Pseudomonas putida* CECT 324^T, *Shewanella hanedai* CECT 5194^T, and *Stappia aggregata* CECT 4269^T.

RESULTS

Sequencing of 16S rRNA Gene

The phylogenetic affiliation using the 16S rRNA sequence analysis was performed on 23 strains isolated from different growing stage of *Ostrea edulis*, surrounding water, and phytoplankton. They were representative within each phenon and some of them from unclustered strains of the previously reported dendrogram (Guisande et al. 2004). For most strains, sequences of the 16S rRNA gene, stretching from nucleotide positions 37–1040 (*Escherichia coli* equivalent), were obtained. These sequences were compared with each other and to related sequences, from the EMBL database, described in Material and Methods. The closest-neighboring species, which shared a similarity value in the 16S rRNA sequences of $\geq 98\%$, were used to identify the isolates. This

led to the identification of 20 strains from 23 selected strains, most of the identified strains belonging to the γ -*Proteobacteria*. Only 3 were not identified, indicating species that have not been sequenced previously. So, the strains 8.98, 34.98, and 38.98 showed pair-wise sequence similarities of less than 95% to their nearest validly named neighbors (Fig. 1) and would probably correspond to new species.

The sequenced strains, geographical areas, and origin of identified species are shown in Table 1.

Phenotypic Characterization

The simplified dendrogram of aerobic strains showing the phena defined with a value of S_j of 74% are presented in Figure 1. The average probability (P) of an erroneous test result (0.02) and the cophenetic correlation coefficient (r) (0.95) were acceptable values. The 60.44% (55/91) of strains were unclustered, and all the species identified by 16S rRNA sequence analysis were grouped into different phenetic clusters or were unclustered. Using the sequence of 16S rRNA gene 40 strains from 75 analyzed were identified. *Pa. undina* and *P. mendocina* included strains that were ungrouped. The strains identified as *Alt. macleodii*, *M. flavimaris*, and *S. waksmanii* were also grouped into separate phena (Fig. 1), confirming the presence of various biotypes in each of those species. The isolates identified as *A. johnsonii*, *H. venusta*, *Pa. piscicida*, and *S. japonica* were each included in one phenon, showing a high phenotypic homogeneity. All these aerobic strains were heterotrophic facultative psychrophilic, showing the same response for 49 tests (from the 87 analyzed), as previously described by Guisande et al. (2004). Characteristics not previously reported and differential tests of the identified species were shown in Table 2. From the 39 new reported tests, 35 were discriminatory to identify species. A selection of 4–15 tests for rapid identification of each species was made after developing a dichotomic differential table of species (Table 2).

DISCUSSION

The 16S rRNA sequence analysis has been used as a successful tool for identifying new strains (Stackebrandt & Goebel 1994, Wiik et al. 1995, Patel et al. 1998, Farto et al. 2003, Montes et al. 2003) and for identifying indigenous bacteria population isolated from the natural environment (González & Moran 1997, Kirchman 2002, Schauer et al. 2003). To clarify the taxonomic status of 75 representative aerobic isolates and select differential biochemical tests for a rapid identification of isolates from oyster culture, the phylogenetic affiliation using the 16S rRNA sequence analysis was performed on 23 strains. These strains were representative within each phenon, and some of them were from unclustered strains. The results showed that some of the isolates identified by sequencing as different species were grouped in the same phenetic cluster, making it difficult to obtain a reliable identification. To establish the phenetic clusters including only one species identified by 16S rRNA sequence analysis, we grouped the aerobic strains of our previous work (Guisande et al. 2004) by numerical taxonomy with a higher S_j (74%) (Fig. 1). These results confirmed a high diversity of aerobic bacteria, as in Mediterranean oyster (*Ostrea edulis*) (Pujalte et al. 1999). The 16S rRNA sequence analysis led to the identification of 20 strains from 23 selected strains and 40 strains from 75 analyzed in this study (Table 2). Thus, both methods, numerical taxonomy and 16S rRNA sequences, were necessary for identification. The first one provided groups of strains

with similar phenotypic characteristics (phenon) and the selection of representative strains within each phenon. The second method led to the molecular identification of each phenetic cluster by the selection of representative strains within each phenon. The combination of both techniques is a useful tool for identifying culturable isolates from unknown habitats with a great diversity. Most of the 16S rRNA sequencing data revealed the close phylogenetic relationship above the level proposed as the intraspecies variability ($\geq 98\%$, Stackebrandt & Embley 2000), and the identification was performed according to the highest phylogenetic similarity value among the sequence of isolates and the reference strains. Moreover, the high number of bases obtained and the bootstrap analysis with 1,000 replicates were used for the identification because of the reliable results it gives and the positive outcome that it has had in phylogenetic studies (Ivanova et al. 2002, Hayashi et al. 2003, Satomi et al. 2003, Thompson et al. 2003, Yoon et al. 2003).

Among the more abundant microbiota associated with Canadian oysters (*Crassostrea virginica*) and Pacific oysters (*Crassostrea gigas*), the genera *Pseudomonas*, *Shewanella* and *Acinetobacter* (Kueh & Chan 1985, Hariharan et al. 1995) were identified by phenotypical tests. We also found these genera in this work (Table 1), however, they were different from those associated with the Mediterranean oyster (*Ostrea edulis*), which were identified by hybridization with phylogenetic probes complementary to conserved regions of 16S rRNA (Pujalte et al. 1999). Unlike other studies, this study is the first research that includes the identification of culturable aerobic microbiota obtained from different stages of *Ostrea edulis* (seed, larval, and reproductive stage). In some cases, the same species was isolated from different stages of oyster and geographical area such as *A. johnsonii*, *M. flavimaris*, *Pa. piscicida*, *Pa. undina*, and *S. waksmanii*, confirming the non-specificity of these species (Table 1). Among the species previously described as isolated from seawater, we have identified at different stages of oyster *Alt. macleodii*, *M. flavimaris*, *Pa. undina*, *S. japonica*, and *S. pacifica* (Gauthier et al. 1995, Ivanova et al. 2001, 2004, Yi et al. 2004, Yoon et al. 2004). Another species typically isolated from sediment, which we identified from oyster larva was *S. livingstonensis* (Bozal et al. 2002). Some other strains identified could be a potential risk for oyster cultures, because those species were associated with fish deaths, such as *Pa. piscicida* (Bein 1954), *P. anguilliseptica* (Doménech et al. 1997) or for human disease such as *A. johnsonii*, usually considered an opportunistic pathogen (Towner 1997, Levi & Rubinstein 1996), or *Pa. tetradonis* that produce a tetrodotoxin (Simidu et al. 1990). We also identified species that could have a probiotic effect on oyster, such as *Roseobacter gallaeciensis* (Ruiz Ponte et al. 1999) and *S. schlegeliana* (Satomi et al. 2003), which were associated with a specific stage of oyster. Its potential use as probiotic should be tested. Finally, we also identified strains such as *P. mendocina* suggesting an earth contamination by soil (Satomi et al. 2003) or *S. waksmanii* showing the colonizing ability of different marine organisms, because other authors reported the association of this species with spincula (Ivanova et al. 2003). Thus, this is the first identification of these species associated with different growing stages of oyster.

Among the species isolated from seawater, we found *A. johnsonii*, *Alt. macleodii*, *H. venusta*, and *Pa. piscicida*. Other species of these genera were previously identified from seawater associated with the culture of *Ostrea edulis* in the Mediterranean by molecular methods (Pujalte et al. 1999). *Alt. macleodii*, *H. venusta*, and

M. flavimaris were also isolated from phytoplankton. The genera *Alteromonas* and *Marinobacter* were also previously associated with phytoplankton by using molecular methods (Alavi et al. 2001, Hold et al. 2001, Seibold et al. 2001, Töbe et al. 2001, Green et al.

2004). The fact of identifying identical species on phytoplankton and oyster is probably a consequence of the process of filter feeding (Kueh & Chan 1985, Hariharan et al. 1995). Only *H. venusta* isolated from seawater and phytoplankton was excluded from oys-

ter, suggesting the inability of this species to colonize this organism (*Ostrea edulis*).

Although there are a limited number of strains isolated from each source, it seems that there is more diversity associated with the larval than with the reproductive stage of oyster when comparing the number of identified species and the total number of identified strains (11/16 and 5/12, respectively; Table 1). However, we cannot evaluate the diversity with the seed, seawater, or phytoplankton, because the number of identified species or the total number of strains is too low (Table 1).

It is difficult to judge how numerically abundant or ecologically significant the species identified actually are, because their representation may simply reflect their selective enrichment in culture and not their numerical abundance. However, these isolates have a representative value as culturable aerobic bacteria associated with the culture of oyster in the NW of Spain because of the high number of strains isolated in different geographical areas over

a long time period. The presence of various biotypes in *Alt. macleodii*, *M. flavinaris*, and *S. waksmanii* adds more phenotypical variability to each species (Farto et al. 1999, Farto et al. 2003, Montes et al. 2003), and this improves their phenotypical description.

A selection of phenotypical tests for rapid identification of potentially pathogenic or probiotic aerobic species was possible by the combination of both techniques. The improved and rapid identification of indigenous aerobic culturable bacteria could be extremely useful in industrial culture plants.

ABSTRACT Outbreaks of lipophilic toxins have been recorded in the north Atlantic coast of Morocco since 1999, but are rare in the Mediterranean coast. Samples of mussels from the Atlantic coast where toxicity was detected by mouse bioassay were stored for further research. Chemical analysis by LC-MS conducted in mussels harvested from this region showed, in addition to the presence of okadaic acid (OA) and dinophysistoxin-2 (DTX2), the presence of azaspiracid-2 (AZA2) as the dominant form of the azaspiracid's (AZAs) family, followed by AZA1 (13% to 26%). AZA3 was rarely detected, and maximal concentrations found were between 3% and 8% of total AZA1/3. The presence of AZA2 and AZA1 was confirmed by mass spectra. Time series corresponding to the summer of 2004 and 2005 showed maximal concentration of AZAs appeared in July in both years. Correlation with occurrence of OA and DTX2, showed both toxin families could appear simultaneously in Moroccan mussels, but maximal concentrations found were always separated in time. This is the first report of azaspiracids in Morocco (NW Africa) and the first report outside of European coastlines.

KEY WORDS: azaspiracids, AZP, Morocco, LC-MS, DSP, mussels, *Mytilus galloprovincialis*

INTRODUCTION

Azaspiracid poisoning (AZP) is a new human gastrointestinal illness discovered in 1995 after consumption of contaminated Irish mussels in the Netherlands (McMahon & Silke 1996). Azaspiracid-1 (AZA1) was the first molecule of the group to be structurally characterized (Satake et al. 1998). Now, at least more than 10 azaspiracid congeners are known (James et al. 2003b). From these, AZA1, AZA2, and AZA3 were the dominant compounds found in shellfish, followed by AZA4 and AZA5. The remaining ones (AZA6–11) were minor components. It is hypothesized so far that these lipophilic toxins accumulate in bivalve molluscs after feeding on the toxic microalgae *Prorocentrum crassipes*, previously considered to be toxicologically harmless (James et al. 2003a).

The symptoms of acute AZP intoxication include nausea, vomiting, severe diarrhea, and stomach cramps (Satake et al. 1998), which closely resemble the symptoms associated with diarrhetic shellfish poisoning (DSP). Toxicological studies showed that repeated administration of AZAs caused prolonged damage in the intestine and induced lung tumors in mice (Ito et al. 2002).

Although shellfish harvested in Ireland provoked the first incidents of human intoxications by azaspiracids, the research in other European countries has led to the discovery of these toxins in shellfish from the United Kingdom, Norway, France, and Spain (James et al. 2002a, Magdalena et al. 2003). Although AZP is a serious concern in Europe, its presence has never been reported outside European waters.

Outbreaks of lipophilic toxins have been recorded in shellfish from the north Atlantic coast of Morocco since 1999, but these toxins are rare in the Mediterranean coast (Taleb 2005). The Moroccan monitoring program to screen for the presence of lipophilic compounds employs the mouse bioassay (MBA), which does not allow distinguishing the contamination from different phycotoxin families, such as DSP or AZP, because these compounds are detected altogether. Although several methodologies exist to study the contamination with DSP, the only methodology available so far to confirm the specific presence of azaspiracids is liquid chroma-

tography coupled to mass spectrometry (LC-MS) (Ofuji et al. 1999). Samples of blue mussels collected in Morocco during the summers of 2004 and 2005 were screened by LC-MS for lipophilic compounds. Besides the presence of DSP toxins (to be reported elsewhere), the presence of azaspiracids was put into evidence and is now reported here for the first time.

MATERIALS AND METHODS

Study Area

Samples of mussels (*Mytilus galloprovincialis*) were collected regularly from Oulad Ghanem and Dar Hamra at the Atlantic coast of Morocco (south of Casablanca, Fig. 1). Digestive glands (DG) were dissected from whole shellfish, homogenized, and extracted for MBA testing. The samples used for the study were selected from those collected in the period of summer outbreaks of samples positive to lipophilic toxins. Digestive glands of positive samples were stored frozen for ulterior analysis by LC-MS.

Sample Preparation and LC-MS Analysis

Digestive glands were homogenized, and a 5-g aliquot was taken and extracted by ultraturax with 20 mL aqueous 90% methanol in a screw-cap plastic centrifuge tube, followed by a 10 min centrifugation at 2500g. A 2-milliliter aliquot of the methanolic supernatant was transferred to 10-mL glass test tubes, washed with hexane (2 × 2 mL), and extracted with dichloromethane (2 × 2 mL). The combined dichloromethane layers were dried with anhydrous sodium sulphate, centrifuged, transferred to small glass test tubes, and dried at 38°C under reduced pressure on a RapidVap (Labconco, USA). After resuspension with 500-μL aqueous 90% methanol, contents were transferred to a 2 mL autosampler vial. Vortex mixing was used in all liquid-liquid and resuspension steps.

Analyses were performed on a LC-MS system from Hewlett-Packard 1100-Series, consisting of an in-line degasser, a quaternary pump, an autosampler, a column oven, and the 1946A single-quadrupole mass detector. High-purity nitrogen was obtained through an N₂-Generator (Dominick-Hunter, Durham, England).

Figure 1. Localization of sampling sites.

A 1.0- μ L aliquot was separated for 12 min on a Merck *Lichrospher-100* RP-18 column (5 μ m, 125 \times 2 mm) protected by a guard column packed with the same material (4 \times 4 mm) using a mobile phase of acetonitrile-water (86:14, v/v), supplemented with 0.05% trifluoroacetic acid, and 50 mM formic acid pumped isocratically at 275 μ L/min. The eluent flow was diverted to waste for 2.0 min after sample injection, and MS detection was carried out from 2.0 min forward. Single ion monitoring (SIM) was used to record the signals from the $[M + H]^+$ ions at: m/z 828.5 (AZA3), 842.5 (AZA1), 844.5 (AZA4, AZA5), and 856.5 (AZA2). Mass spectra were obtained scanning in the range m/z 600–900.

Dr. Phillip Hess and Dr. Terry McMahon, Marine Institute, Ireland, supplied a pure standard of AZA1 and mussels contaminated with AZA1–5.

RESULTS

Analysis carried out in SIM mode for azaspiracids in mussel DG collected in the Atlantic coast of Morocco showed the presence in some samples of azaspiracid-2 (AZA2), followed by a minor contribution of AZA1. Only in samples where the concentration of AZA2 was highest, it was possible to detect also AZA3 (Fig. 2a). Analysis in SCAN mode of the most contaminated samples allowed the confirmation of AZA1 and AZA2 by mass spectra (Fig. 2b, c, respectively). AZA3 was not found in concentrations enough to allow confirmation by mass spectra. Although the presence of AZA4/5 was screened, no evidence of their presence was registered.

The temporal evolution of AZAs was studied in mussels collected in Oulad Ghanem in 2004 and 2005 (Fig. 1). In 2004, concentration of AZA2 and AZA1 was maximal in the beginning of July, then declined, and in autumn increased again (Fig. 3a). In 2005, the major peak of AZAs occurred again in mid July, and throughout the summer it remained fairly constant from 0.20 μ g/g down to 0.10 μ g/g (Fig. 3b). A similar evolution of toxic profiles was obtained with mussel samples collected in Dar Hamra in 2005 (data not shown). AZA2 was in all samples tested the dominant toxin (Fig. 3c, d). When detected, levels of AZA1 fluctuated between 13% and 26% (Figs. 3c, d). Only in samples from 2005 AZA3 was detected, and maximal concentrations found were between 3% and 8% (Fig. 3d).

The evolution of the summed concentrations of AZAs in mussels collected in Oulad Ghanem in 2004 and 2005 was compared with the concentration of DSP toxins found in the same samples, corresponding to the sum of hydrolyzed OA and DTX2 (data to be reported elsewhere). From the data presented in Figure 4, one observes that maximal concentrations of AZP toxins appear after the decline of DSP peaks (mid September 2004 and mid July 2005). Because data for the early summer of 2004 is incomplete, it is not possible to conclude if the AZA's peak from mid July

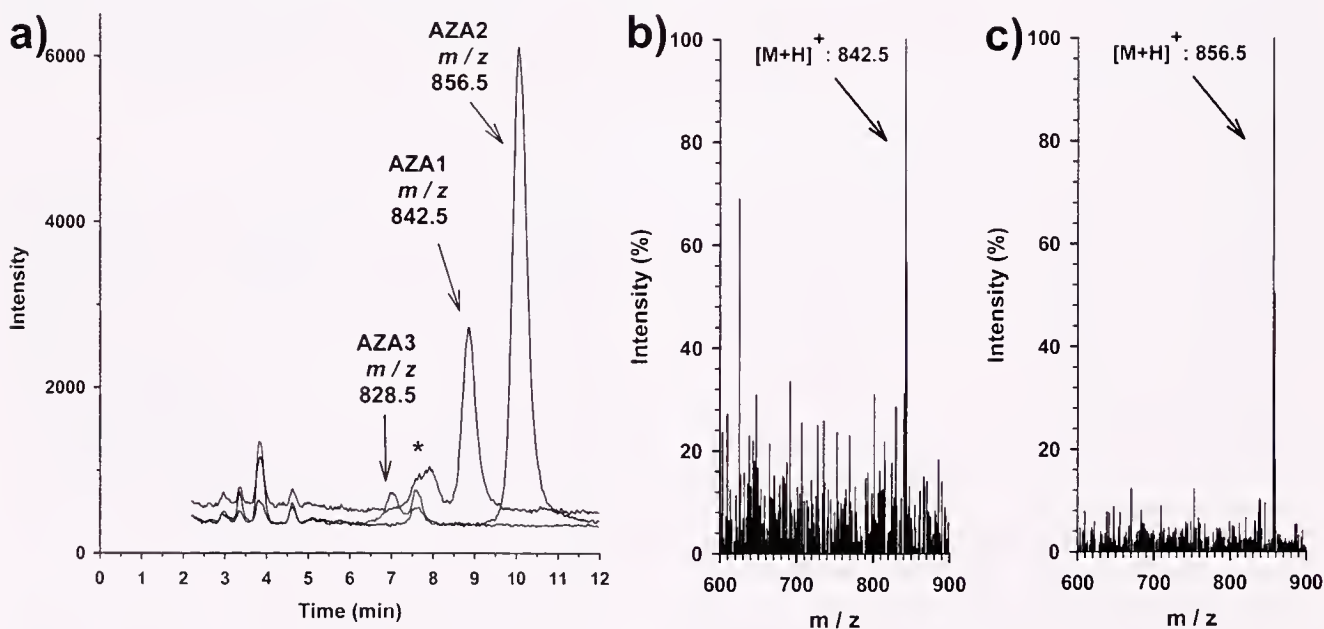

Figure 2. LC-MS analysis of mussel DG from Jemâa Ouled Ghanem collected on July 2005 (a) superposition of three SIM signals: m/z 828.5 (corresponding to AZA3), 842.5 (AZA1), and 856.5 (AZA2); (b) and (c), mass spectra of AZA1 and AZA2, respectively, obtained from the same sample analyzed in SCAN mode.

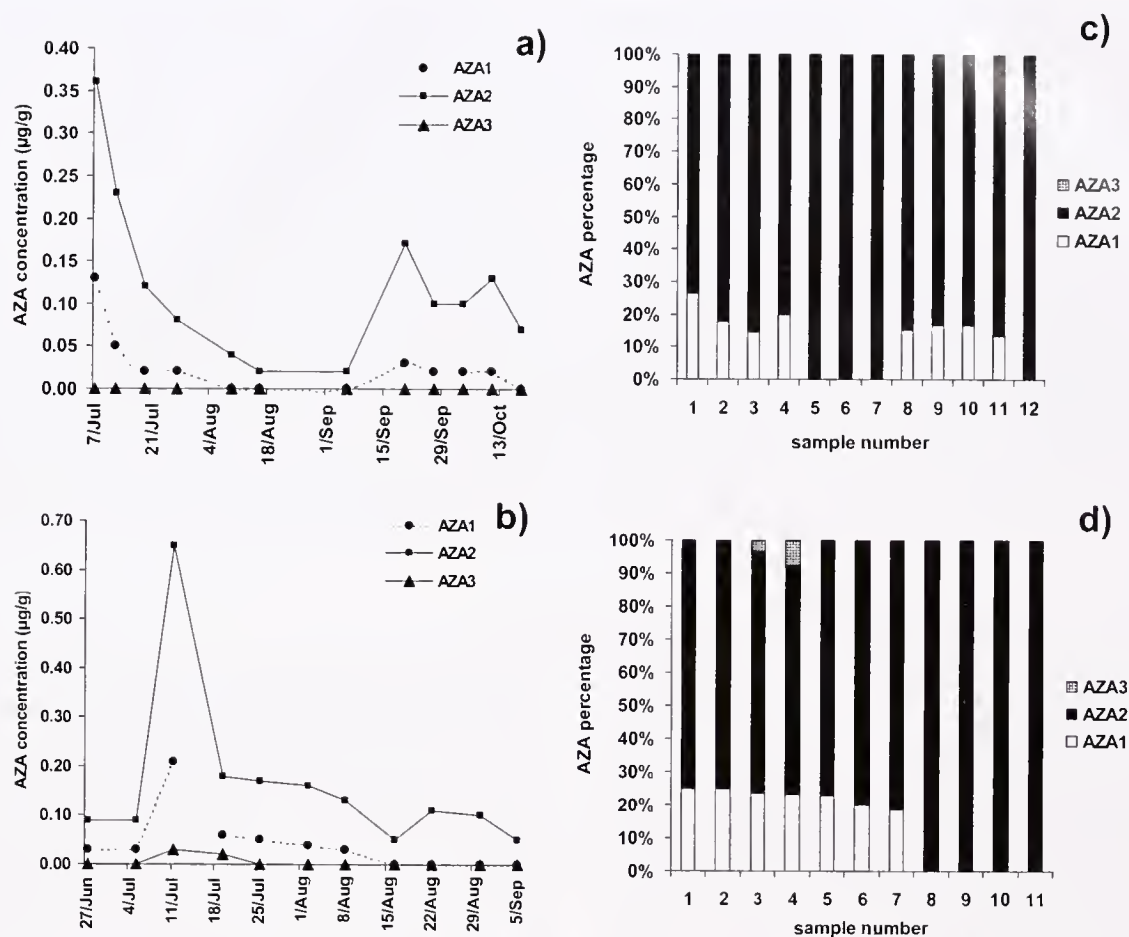

Figure 3. Evolution of AZAs concentration in mussel digestive glands collected in Jemâa Ouled Ghanem in (a) 2004, (b) 2005 and evolution of their respective percentages (c) and (d).

follows a declining DSP peak, or simply precedes a new DSP raising peak.

DISCUSSION

This study reports for the first time the presence of azaspiracids in the NW African coast, and is the first time AZAs are reported

in shellfish from such low latitude (32°50'904N, 8°53'500W) and outside Europe. The presence of AZA2 in shellfish from the south coast of Portugal was previously suspected, but the low levels found of the suspect compounds did not allow their unambiguous confirmation, mainly because that study used whole flesh (Vale 2004). According to Hess et al. (2005), these toxins are on average

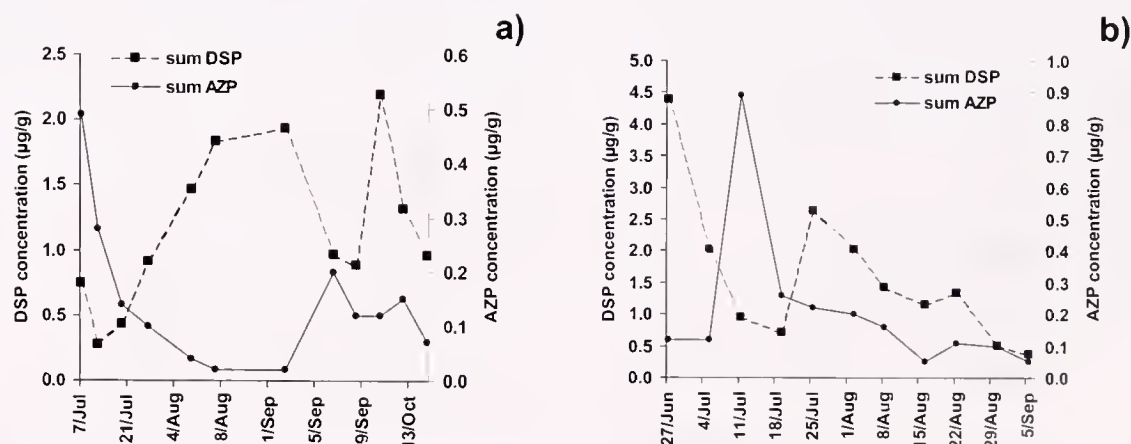

Figure 4. Comparison between concentration of DSP toxins and AZP toxins in mussel digestive glands collected in Jemâa Ouled Ghanem in (a) 2004, (b) 2005.

circa 5 times more concentrated in DG, compared with the whole mussel.

The simultaneous presence of DSP and AZP toxins may occur in Moroccan mussels, but maximal concentrations of these two distinct toxin families are separated in time. Evidence from Irish mussels points also that contamination with AZP may follow contamination with DSP (Clarke et al. 2006), but appearance of AZP before the rise in DSP toxins may also occur (Hess et al. 2002). Because the species hypothesized to produce AZAs is known to be heterotrophic, its growth might depend on the appearance of conditions that favor the blooming of certain algae species necessary for predation, amongst which also proliferate the DSP producers.

In the Atlantic Moroccan coast, the occurrence of AZP seems to be recurrent, and maximal levels may take place over the summer, although other seasons of the year were not studied yet for the presence of AZP. After the launching of the lipophilic toxin monitoring along the Moroccan coast by mouse bioassay (MBA), the recurrence of lipophilic toxin outbreaks in the Atlantic coast was recorded during the summer time almost every year since 1999,

but in the Mediterranean coast occurrence of this type of toxins is rare (Taleb, 2005). For the moment, at least two families of lipophilic compounds are implied in the observed mouse bioassay toxicity. So far, these are the most relevant families of toxins for public health, as other families, such as yessotoxins and pectenotoxins, do not seem to be relevant for human health because of their low oral potency (Anonymous 2004).

The toxin profiles found in European shellfish (hepatopancreas) and plankton samples have been dominated by AZA1 (James et al. 2002a, James et al. 2003a, Magdalena et al. 2003). However, AZA3 has been reported to be the most abundant toxin in meat samples with the hepatopancreas excised (James et al. 2002b). Although variations in toxin profile have been observed, the results reported here of AZA2 dominance might point to a difference in the phytoplankton-producing species. Indeed, the finding of AZAs at such low latitudes may raise the question if more than one species is involved in AZA production and also concerns of a more universal distribution of AZAs than previously believed.

MICROSCOPIC ANATOMY OF FOOT OF THE SPINY TOP SHELL, *BATILLUS CORNUTUS* (LIGHTFOOT, 1786) (GASTROPODA: TURBINIDAE)

GUI KWON JUNG, JUNG JUN PARK, JAE WOO LEE, AND JUNG SICK LEE*

Department of Aqualife Medicine, Chonnam National University, Yeosu 550-749, Korea

ABSTRACT Foot structures of the spiny top shell, *Batillus cornutus* were investigated by light and transmission electron microscopy. The foot was composed of epithelial layer, connective tissue layer, and muscular layer from outside inward. The epithelial layer was multiple-folded and simple and was composed mostly of columnar and mucous cells. Epithelial layer thickness was approximately 40 μm in the pedal body and approximately 30 μm in the opercular zone. Distribution of mucous cells in the epithelial layer was found to be higher in the opercular zone than those in the pedal body. Mucous cells contained acidic material abundant in sulfate and carboxylate group, from the results of AF-AB reaction. From TEM observation, the epithelial layer is composed of epithelial cell, ciliated cell, absorptive cell, and secretory cell. Secretory cells can be classified into six types (A, B, C, D, E, F) in accordance with the shapes and ultrastructural characteristics of secretory granule. Type A secretory cell is the most abundant cell of the six types of secretory cells. The type of muscle fibers was mostly smooth muscle fibers. Muscle fibers can be divided into two types, one that is composed only of thin microfilaments and the other composed of thin and thick microfilaments.

KEY WORDS: foot, microscopic anatomy, *Batillus cornutus*, TEM, top shell

INTRODUCTION

The top shell, *Batillus*, belongs to Turbinidae of Gastropoda, and it is widely distributed throughout temperate coastal waters to tropical coastal waters including the Pacific, Indian, and Atlantic Ocean. Among these, spiny top shell, *Batillus cornutus* is a settled gastropod thriving in the waters of the southern part of the East Sea and coast of Cheju Island in Korea, southern coastal waters of Japan, and reef ridden coastal waters of the Yellow Sea of China. The spiny top shell is one of the most important food resources in Korea, along with abalone, placing it at a very important position industrially (Yoo 1988).

The foot of the gastropod is an organ with flexibility corresponding to the motile system, and it performs functions such as mobility, attachment, capturing of food, mating, spawning, and shell cleaning (Voltzow 1994). The foot is composed of muscular tissue and nerve bundles, and it is partially covered by an operculum (Bullock 1965).

Study on the pedal and muscular structure of the gastropod includes reports on *Patella vulgate* (Jones & Trueman 1970), *Neritina reclivata* and *Thais rustica* (Gainey 1976), *Patella vulgate* and *Acmaea tessulata* (Grenon & Walker 1978), *Bullia digitalis* (Trueman & Brown 1976, 1987), *Bullia rhodostoma* (da Silva & Hodgson 1987), patellid limpets (Frescura 1987; Frescura & Hodgson 1990a, 1990b), *Busycon contrarium* and *Haliotis kamtschatkana* (Voltzow 1990), and *Nassarius kraussianus* (Trueman & Hodgson 1990).

However, in relation to these studies, there is no biological study on the foot structure of the spiny top shell, *Batillus cornutus*. Therefore, this study aims to describe the ultrastructure of the foot of the spiny top shell and to provide basic information for future study on structural changes of the foot in accordance with environmental and physiological changes.

MATERIALS AND METHODS

The spiny top shells were collected by divers in the coastal waters of Modori, Cheongsanmyeon, Wandogun, Cheollanamdo Korea (N 34°13', E 126°47') (Fig. 1) May 2003. Thirty spiny top

shells in shell height 60.0–69.9 mm were used in this study. The sampled individuals were measured, the shell removed, and the pedal tissue was fixed after dividing into the pedal body and opercular zone (Fig. 2).

For light microscopy the tissues were fixed in Bouin solution and then prepared according to the following paraffin methods: H-E double stain, Masson trichrome stain, PAS reaction, AB-PAS (pH 2.5) reaction, Alcian blue (pH 1.0) reaction, and AF-AB reaction were used for sections.

For transmission electron microscopy the specimens were fixed in 2.5% glutaraldehyde solution (pH 7.2 buffered in 0.1M phosphate buffer) for 2–4 h at 4°C and postfixed in 1% osmium tetroxide (OsO_4) solution for 2 h at 4°C. After fixation the specimens were washed in 0.1 M phosphate buffer, dehydrated by ethanol step-by-step, and finally embedded in Epon 812. Ultrathin sections (70 nm in thickness) were put on copper grids (200-mesh), double stained with uranylacetate and lead citrate, and finally examined using a transmission electron microscope (JEM-1200EXII, JEOL).

Stain affinity of the mucous cell was determined by using the Pantone Formula Guide (Pantone Inc. USA) as standard, and its unique code was indicated in parenthesis. Image analyzer (IMT, Visus, USA) was used to quantify the histological characteristics.

RESULTS

The foot of the spiny top shell is the organ that extends from the dorsal side of the anterior portion of the body and continues onto the head. Overall color of the foot was dark brown and the portion

attached to the operculum was a wrinkled light orange-colored muscular mass.

Histological structure of the foot was composed of an epithelial layer, connective tissue layer, and a muscular layer from outside inward. The epithelial layer was a simple multiple-folded layer composed mostly of columnar and mucous cells (Figs. 3, 4).

The epithelial layer was approximately 40 μm thick in the pedal body and approximately 30 μm in the opercular zone (Fig. 5). A well-developed striated border was formed on the free surface of the epithelial layer (Fig. 3B). Mucous cells were observed between columnar epithelial cells in the epithelial layer, and these cells exhibited vacuoles in H-E stain and Masson triple stain (Figs. 3A, B; 4A, B).

Mucous cells reacted weakly in PAS reaction in the pedal body (Fig. 3C) and opercular zone (Fig. 4C). However, mucous cells revealed a blue color (300 C) in AB-PAS (pH 2.5) reaction (Figs. 3D; 4D) and AF-AB reaction (pedal body: 2995 C; opercular zone: 306 C) (Figs. 3F; 4F). Distribution of mucous cells in the epithelial layer was found to be higher in the opercular zone than those in the pedal body (Fig. 6).

The connective tissue layer appeared very weak between the epithelial and muscular layer (Fig. 1B).

The muscular layer is composed of connective tissue and muscular fiber bundles with the presence of hemolymph sinus. Muscular fiber bundles were distributed regularly in horizontal and vertical directions, with higher density in the opercular zone than in the pedal body (Fig. 4B).

From TEM observation, the epithelial layer is composed of epithelial, ciliated, absorptive, and secretory cells.

Epithelial cells were columnar and approximately 30 μm in height both body and opercular zone of the foot (Figs. 7A, C). In addition, microvilli of approximately 2 μm height were developed commonly on the free surface of epithelial cells, and tight junctions of apical lateral aspect and membrane interdigitations were found between the epithelial cells (Fig. 7B). However, these columnar epithelial cells displayed differences in shapes and positions of the nucleus. In the columnar epithelial cell of the pedal body, the shape of the nucleus was irregular and oval-shaped and located in the middle or basal portion of the cell (Fig. 7A). In comparison, the nucleus of the columnar epithelial cell in the opercular zone had an elongated oval-shape with length equivalent to 2/3 of the cell length (Fig. 7C).

Ciliated cells were better developed in the epithelial layer of the body than those of opercular zone of the foot. These ciliated cells have well-developed cilia on the free surface. The length of these cells was approximately 45 μm and the cilia length was approximately 4 μm . These cells have a rectangular-shaped nucleus of approximately 17 μm in the basal portion (Fig. 8A). Tubular mitochondria are clustered in the upper portion of the cytoplasm, and the ciliary rootlet is connected to mitochondria (Fig. 8B). Cross section of the cilia showed "9+2" microtubular structure of approximately 200 nm in diameter (Fig. 8C).

Cells with absorptive function that is rarely observed in the epithelial layer have microvilli on the free surface; and several pinocytotic vesicles, multivesicular bodies, and mitochondria were found in the upper portion of cytoplasm (Fig. 8D).

Cm, circular muscle; Ct, connective tissue; E, epithelium; El, epithelial layer; Lm, longitudinal muscle; Mc, mucous cell.

Secretory cells can be classified into 6 types (A, B, C, D, E, F) in accordance with the shapes and ultrastructural characteristics of secretory granule.

The type A secretory cell (Fig. 9A) is the most abundant cell of the six types of secretory cells. These cells have membrane-bounded secretory granules, and the granules had higher electron density in comparison with the secretory granules of other secretory cells (Fig. 9B). Furthermore, numerous rough endoplasmic reticula were found in the basal cytoplasm of these cells (Fig. 9A).

The type B secretory cell is circular. Electron density of the secretory granule was low, and the internal space of the secretory granule was filled with fine granular substances. The distribution of these cells was lower than the type A secretory cell but higher than all other secretory cells (Fig. 9C).

The type C secretory cell is clavate shaped. The nucleus of these cells was irregularly shaped and smooth endoplasmic reticula were scattered in the cytoplasm. Shape of the secretory granules was diverse, and the electron density was low (Fig. 9D).

The type D secretory cell is columnar with the nucleus located in the basal portion. Secretory granule of the cells did not have a

membrane, and the electron density was the lowest among the six types of secretory cells (Fig. 9E).

The type E secretory cell is circular. Rough endoplasmic reticula and secretory granules with diverse and lower electron density were scattered in the cytoplasm (Fig. 9F).

The type F secretory cell is oval-shaped. The distribution of these cells was the lowest among the six types of secretory cells. The secretory granule contained vacuoles with various electronic densities (Fig. 9G).

Numerous collagen fibers, fibrocytes, some muscle fibers, and hemocytes were observed in the connective tissue layer (Figs. 10A, B).

Some collagen fibers were observed in the muscular layer. In the longitudinal section, although the electron density was low, some transverse striations were distinguished in the collagen fibers (Fig. 10C).

Several types of muscle fibers were arrayed in various directions in the muscular layer, and they were mostly smooth muscle fibers. Muscle fibers can be divided into two types, one that is composed only of thin microfilaments and the other composed of

Figure 5. Epithelial layer thickness of the foot of the spiny top shell, *Batillus cornutus*.

Bm, basal membrane; Mi, membrane interdigitations; N, nucleus.

thin and thick microfilaments. The former showed high-level distribution. The density of microfilament in the muscle fiber illustrated slight difference (Fig. 10D).

Muscle fibers composed of thin filament were categorized into two types. One type was composed only of muscle fibers with same electron density, and the other type was composed of muscle fibers with higher electron density in the cortex and lower electron density in the medulla (Fig. 10E). Thin filament muscle fibers were composed mainly of microfilaments approximately 20 nm in diameter. These have tubular mitochondria and a small number of sarcoplasmic reticula around the sarcolemma and some glycogen granules in the sarcoplasm (Fig. 10F).

In the muscle fiber in which thin and thick filament were mixed, the thin filament was approximately 10 nm in diameter, whereas that of the thick filament was 80 nm. Distribution of mitochondria and sarcoplasmic reticula in these muscle fibers was lower than the muscle fiber that was composed only of thin filament (Fig. 10G).

In addition, nerve cells were found between collagen fibers of the muscular layer (Fig. 10H).

DISCUSSION

The foot of the gastropod is composed of the epithelial layer, connective tissue layer, and muscular layer. The epithelial layer is

Figure 8. Ultrastructure of the pedal epithelial layer of the spiny top shell, *Batillus cornutus*. (A) Longitudinal section of ciliated columnar cell, $\times 3,000$. simple and composed of columnar epithelial and secretory cells. The connective tissue layer is relatively thin. In addition, the muscular layer is composed mainly of collagen fibers and smooth muscle fibers (Bullock 1965, Grenon & Walker 1978, da Silva & Hodgson 1987, Trueman & Hodgson 1990).

In this study, it was also found that the foot of the spiny top shell, *Batillus cornutus* was composed of epithelial layer, connective tissue layer, and muscular layer from exterior inward in cross section. The epithelial layer was simple and composed of columnar and mucous cells. Well-developed circular muscle, longitudinal muscle, and hemolymph sinus was observed in the muscular layer.

Generally, mucous cells in the epithelial layer of the mollusc foot contain acidic glycosaminoglycans within the sulfate and carboxylate group (Eble 2001). This study confirmed that the mucous cells contained acidic material abundant in the sulfate and carboxylate group from the results of AF-AB reaction.

Among gastropods, limpet, *Acmaea tessulata* had six types of secretory glands in the foot. The secretory substance is weakly acidic mucopolysaccharide and correlates with mobility function. *Patella vulgata* on the other hand has nine types of glands. Among these, six types are distributed in the foot, and contain weak acidic mucopolysaccharide and correlates with mobility function. The other three types are sole glands with highly viscous acidic mucopolysaccharide and attachment function (Grenon & Walker 1978).

In this study, 6 types (A, B, C, D, E, F) of secretory cells were

distinguished in the epithelial layer of the foot. Among these, C, D, and E type were observed mostly in the opercular zone, enabling one to predict that these cells are associated with operculum formation.

Although the muscle fiber of molluscs, in comparison with the vertebrates, is limited, transverse striations are found in some smooth muscle cell (Lowy & Vibert 1967; Millman & Bennett 1976; Sobieszek 1973). Characteristics of muscle fiber are diverse and contain paramyosin (Chantler 1983).

Types of muscle fiber composing the foot muscle of mollusc are categorized based on the arrangement of dense body, distribution of thick filament, ratio of thick microfilament and thin microfilament, invagination of sarcolemma, composition of sarcoplasmic reticula, and mitochondrial arrangement (Nicaise & Amselem 1983). Foot muscle of *Batillus rhodostoma* of Turbinidae illustrates intermediate type of muscle forms found in some reported molluscs (Lowy & Vibert 1967, Sobieszek 1973).

The foot muscle of *Nassarius kraussianus*, a gastropod, is composed mostly of smooth muscle fibers and collagen fibers. Although there were some muscle fibers with 4–9 μm in diameter, the majority had 3–4 μm in diameter, and has numerous membrane interdigitations between each cell. Muscle fiber is composed of thick filament with density of $131 \pm 9.1 \mu\text{m}^{-1}$, $40.6 \pm 4.1 \text{ nm}$ in diameter, and length of 7–10 μm . Well-developed weakly acidic glycogen granules of 2 μm in length and 0.5 μm in diameter are found in the sarcoplasm (Trueman & Hodgson 1990).

Figure 10. Ultrastructure of the pedal connective tissue and muscular layer of the spiny top shell, *Bartillus cornutus*: (A) Section showing the epithelial layer (E) and connective tissue (Ct). $\times 3,000$. (B) Section showing the collagen fibers (Cf) and muscle fibers in the connective tissue layer. $\times 12,000$. (C) Longitudinal section of collagen fiber. $\times 120,000$. (D) Section showing the various muscle fibers (Muf) in the muscular layer. $\times 2,500$. (E) Cross section showing the two types of muscle fiber composed of thin filament. $\times 15,000$. (F) Longitudinal section of muscle fiber composed of thin filament showing the tubular mitochondria (Mt), sarcoplasmic reticula (Sr) and some glycogen granules (Gg). $\times 25,000$. (G) Cross section showing the muscle fiber of composed of thin filaments (Tnf) and thick filaments (Tkf) $\times 40,000$. (H) Nervous cell in the muscular layer. $\times 12,000$. Ax, axon; Bl, basal lamina; Db, dense body; Ne, nerve ending.

In the foot muscle of the whelk, *Bullia rhodostoma* of Nassariidae of Gastropoda, two types of muscle fibers, namely A and B types were distinguished. Among these, A-type is striated muscle fiber observed mainly in propodium, which enables fast shortening of the foot when crawling or burrowing. Dense body (94.70 ± 7.50 nm in diameter) of the A-type muscle fiber is arranged vertically along the long axis of the muscle fiber. Ratio of thin filament to the thick filament is more than 1:10 and the mitochondrial area is approximately 25%. The B-type is of smooth muscle fiber type that is mostly found in the metapodium, and functions to maintain greater tension. Dense body is rarely found in the B-type muscle fiber. The diameter of the dense body is 84.40 ± 2.47 nm with irregular arrangement. Ratio of thin filament to the thick filament is approximately 1:12–1:30 with mitochondrial area at 35%. The mitochondrial distribution in the A-type muscle fiber is a dispersed pattern, whereas that in the B-type muscle fiber is clustered (da Silva & Hodgson 1987).

Frescura & Hodgson (1992) categorized the muscle fibers of columellar muscles of six species (*Bullia rhodostoma*, *Burnupena cincta*, *Haliotis spadicea*, *Siphonaria capensis*, *S. concinna*, *Turbo sarmaticus*) belonging to Prosobranchia into Type I and Type II. Muscle fiber of Type I has small number of dense body, mito-

chondria and sarcoplasmic reticula. Thin and thick filaments are irregularly mixed in these muscle fibers. The diameter of thick filament measured in the preparation was 26 nm for *Turbo sarmaticus* and 69 nm for *Burnupena cincta*, illustrating differences depending on the species. In comparison, muscle fibers in the Type II category are composed of thin filament and have a striated appearance. These muscle fibers are connected with collagen fibers and exhibit difference in the development of cell organelles.

In this study, transverse striations were not clearly observed in the muscle fiber of the foot of the spiny top shell. Types of muscle fiber were distinguished into a type in which thin and thick filaments were present in mixture and the other type composed only of thin filament. It was determined that these two types corresponds to the "Type I" and "Type II" muscle fiber reported by Frescura & Hodgson (1990a, 1990b, 1992). Such result of this study and distribution of thick filament, invagination of sarcolemma and arrangement of dense body, and sarcoplasmic reticula and mitochondria illustrated the same features as previous reports. However, the finding that muscle fiber composed only of thin filament is categorized into two types is deemed to be a characteristic of muscle fiber of the spiny top shell, *Bartillus cornutus*.

BIODIVERSITY OF SESSILE AND MOTILE MACROFAUNA ON INTERTIDAL OYSTER REEFS IN MOSQUITO LAGOON, FLORIDA

MICHELLE L. BOUDREAUX,^{1*} JENNIFER L. STINER² AND LINDA J. WALTERS

Department of Biology, University of Central Florida, 4000 Central Florida Boulevard, Orlando, Florida 32816; ¹Everglades Partners Joint Venture, 701 San Marco Blvd. Suite 1201, Jacksonville, Florida 32207; ²BCI Engineers & Scientists, 2000 E. Edgewood Drive Suite # 215, Lakeland, Florida 33803

ABSTRACT Our research focused on determining the diversity and abundance of sessile and motile macrofauna that use intertidal reefs of the eastern oyster *Crassostrea virginica* for feeding, settlement space or refuge in Mosquito Lagoon, Florida. Five replicate lift nets were deployed at six sites (three impacted reefs with seaward margins of disarticulated shells, three reference reefs without dead margins) to determine the species composition and numbers present on these reef types. All nets were deployed intertidally on backreef areas on living oyster reefs, just above mean low water. One and a half liters of live oysters and oyster shells were placed in each net (1 m²) on deployment. Nets were surveyed for all fauna monthly for one year. Metrics used to evaluate habitat use were species richness (total number of different species found) and density (total number of organisms per net). Comparisons were also made between community assemblages found on the two different types of reefs in the area (with and without dead margins) and for sessile species, recruitment on living oysters versus disarticulated shells. Forty sessile and 64 motile species of macroorganisms were found utilizing the oyster reefs in Mosquito Lagoon. However, recruitment on live oysters was twice that on disarticulated shells. Significant temporal variations were documented. When the two reef types were compared, however, no differences were found.

KEY WORDS: oysters, *Crassostrea virginica*, habitat use, fishes, decapods, barnacles, invertebrates, lift nets

INTRODUCTION

Human activities threaten the productivity, diversity, and survival of coastal resources, leading to a growing need to understand and manage all coastal zones (e.g., Jackson et al. 2001). The Indian River Lagoon system (IRL) on the east central Florida coast is one such place. This estuary extends 251 km, from Ponce de Leon Inlet to Jupiter Inlet. The Lagoon system is a series of three distinct, but connected, estuaries: the Indian River, the Banana River and Mosquito Lagoon. This lagoon system may contain the richest biota of any estuary in North America (Provan et al. 1992). It supports over 3,000 animal and plant species, 50 of which are listed as threatened or endangered. Commercially important intertidal reefs of the eastern oyster *Crassostrea virginica* are common in this estuarine system.

Diversity is extremely high in the IRL because of its location within a zoogeographic transition zone (e.g., Walters et al. 2001, Smithsonian Institution 2006). Researchers have documented the substantial species diversity of many habitats and taxa in IRL waters: seagrass and its associated organisms (e.g., Virnstein et al. 1983, Dawes et al. 1995); finfish (Gilmore 1977, Gilmore 1995, Tremain & Adams 1995); elasmobranchs (Snelson & Williams 1981) and decapods (Smithsonian Institution 2006). To date, there have been no studies of the biodiversity on intertidal oyster reefs in the IRL.

Three-dimensional reef structures of *Crassostrea virginica* are created by years of successive settlement of larvae on adult shells (Dame 1996). Through its structural complexity, these ecosystem engineers create heterogeneity that is rare in marine systems dominated by soft-bottom habitats (e.g., Bartol et al. 1999, Micheli & Peterson 1999). Organisms use oyster reefs for many different reasons; mobile species may: (1) feed directly on live oysters, (2) use shell surfaces for spawning and (3) seek refuge from predation

within oyster clusters (e.g., Tolley & Volety 2005), whereas sessile species use oyster reefs for attachment space.

Previous studies on intertidal oyster reef biodiversity include: Wells 1961 (North Carolina), Dame 1979 (South Carolina), Bahr and Lanier 1981 (south Atlantic coast), Crabtree and Dean 1982 (South Carolina), Wenner et al. 1996 (South Carolina), Coen et al. 1999a (South Carolina), Posey et al. 1999 (North Carolina), O'Beirn et al. 2004 (Virginia) and Tolley et al. 2005 (Florida, Gulf of Mexico). In most of these studies, the primary focus was on motile species (fish and crustaceans). Our study adds to this database by investigating the recruitment of motile macrofauna on backreef regions of intertidal oyster reefs of *Crassostrea virginica* in the IRL system along the Atlantic Coast of Florida. In addition, this is the first study in Florida to quantify diversity and abundance of all sessile macrofauna on oyster reefs.

METHODS

Study Site

All research was conducted in Mosquito Lagoon, within the boundaries of Canaveral National Seashore (28°0.68'N; 80°52.06'W) (Fig. 1). Except where dredged, the average depth of the Lagoon is less than 1 m and the current is primarily wind-driven (Walters et al. 2001). Annual salinity ranges between 18 and 45 ppt, depending on rainfall (Grizzle 1990, Walters et al. 2001).

Within a 5-y period (1998–2003), the number of recreational boat registrations within the counties that border Mosquito Lagoon increased by 43% (Wall et al. 2005). This increasing intensity of year-round boating has helped create piles of disarticulated shells (dead margins) on the seaward edges of oyster reefs along major navigational channels in these shallow waters (Grizzle et al. 2002, Wall et al. 2005). We compared back-reef areas on reefs with and without dead margins to determine if recreational boating pressures influenced biodiversity.

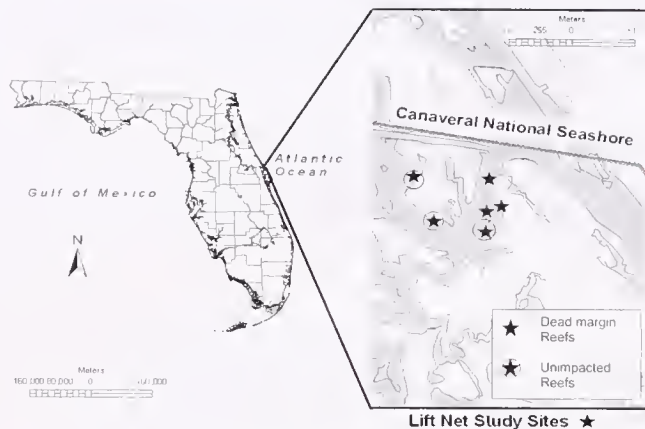

Figure 1. Lift nets study sites in Mosquito Lagoon, Florida.

Lift Net Field Sampling

Six oyster reefs were selected for this study, three impacted reefs (with dead margins) and three reference reefs (without dead margins). All were within a 5-km radius (Fig. 1). Five replicate lift nets were placed on the back-reef area of each reef. The protected back-reef areas were chosen to minimize the loss of nets caused by water motion.

Lift net methods were adapted from Crabtree and Dean (1982), Coen et al. (1996a), and later modified by Tolley et al. (2005) for use in Florida systems. We further modified the protocol to include the enumeration of sessile species recruiting to oyster reefs. Lift net frames were 1 m² and created from 3.8 cm diameter PVC. The nets were 0.5 m deep. The sides of the nets were made from 3.2 cm diameter opening mesh and the bottom was made from a 1-m square of 0.2-cm diameter opening mesh. The two mesh sizes were machine-sewed together using extra strength cloth thread. The sewn mesh was attached to the PVC frame with cable ties (tensile strength: 11 kg).

Lift nets were deployed intertidally, just above mean low water, on living oyster reefs. Volume normalized oysters and oyster shells in good condition (1.5 L) were placed in the lift nets. Half (0.75 L) were single, disarticulated shells from adults (Mean \pm SE length: 77.5 \pm 1.4 mm; weight: 21.5 \pm 1.1 g) and half were similar-sized live clusters collected from the oyster reef. All were mechanically scraped clean of epiflora and epifauna. New shells and clusters were placed into the nets each month. Additionally, at the time of net retrieval, all nets were cleaned to remove organisms that had settled on the mesh or PVC frames.

Lift nets were retrieved by swiftly picking up the nets on two sides and collecting all recruited motile and sessile organisms. In the laboratory, we identified all organisms within 24 h and returned them alive to Mosquito Lagoon. Only sessile organisms attached to oyster shells within the lift nets were counted. Nets were collected monthly for 12 mo (June 2004 to July 2005). No data was collected for September 2004 because Hurricanes Charley, Jeanne and Frances required removal of nets and prevented data collection. Specimens of each species were preserved in 70% isopropanol to create a species archive for the University of Central Florida.

Environmental Variables

Permanent temperature monitors (Onset Stowaway Tidbit Temperature Loggers) were attached to cinder blocks and de-

ployed at each site in water at the same depth as the lift nets. Temperature data were collected once each hour. Salinity was measured on net retrieval using a portable refractometer. Three sediment traps were deployed at each site at the same depth as the lift nets to determine sediment load accumulations during the 4-wk intervals between sampling. Each replicate, cylindrical PVC pipe sediment trap (10-cm diameter \times 25 cm deep) was submerged flush with the substrate (Lenihan 1999). We capped traps underwater at the time of retrieval. The sediment traps were retrieved concurrently with the lift nets and new traps were immediately deployed to replace them. Total sediment mass was determined by drying samples at 60°C for 48 h in a drying oven (Econotherm Model Number 51,221,126) and weighing contents on a top-loading balance (O'Haus Scout 2-Model Number SC6010). Relative grain size was determined by grinding the dried sediment and sorting samples with a sieve (0.062 mm) to separate the silt/clay from the sand/gravel fractions.

Analyses

For all cases where analysis of variance (ANOVA) tests were run, prior to running the ANOVAs, homogeneity of variance and normality were tested using Levene and Kolmogorov-Smirnov tests. If significant differences were found with ANOVA, *post-hoc* Tukey-Kramer tests were run. Data assumptions of variance and normality were met for all ANOVAs at the $P = 0.05$ level, thus the data were not transformed.

Sessile Macrofauna

Response variables of species richness (total number of different species) and density (total number of individuals) were analyzed using a 4-way, nested, ANOVA. The factors in the nested ANOVAs were: (1) reef type (reefs with dead margins or reference reefs), (2) month, (3) site and (4) shell type (disarticulated shells or live oysters in clusters). Reef type, month and shell type were fixed factors, whereas site was random. Shell type was nested within site, and site was nested within reef type.

Motile Macrofauna

Community metrics of motile species were similarly examined with a 3-way ANOVA. Response variables of species richness and density were examined as in sessile species. For each ANOVA, the factors were reef type (fixed), site nested within reef type (random), and month (fixed).

Sediment Loads

A 3-way ANOVA was conducted to test whether sediment loads on oyster reefs varied as a function of the following fixed factors: reef type (reference or dead margins) and month. The third factor, site, was random and nested within reef type.

RESULTS

Biodiversity and Composition

Sessile Macrofauna

Twenty-five species of sessile invertebrates recruited to oysters and oyster shells in the lift nets during our study (Table 1). Barnacles in the genus *Balanus* (Arthropoda) dominated all samples numerically. Tube worms in the genus *Hydroides*, the jingle shell *Anomia simplex*, the eastern slipper shell *Crepidula astraolea*,

Chordata															

and the eastern oyster *Crassostrea virginica* were also very abundant (Table 1). Mollusca represented the most abundant phyla, with nine species found. Other phyla represented included Annelida, Cnidaria, Porifera, Ectoprocta and Chordata (Table 1). Outside of the lift nets, 15 additional species of sessile organisms were found in small numbers on the intertidal oyster reefs and nearby subtidal areas throughout the course of our study in Mosquito Lagoon, although they do not represent any additional phyla (Table 2).

Measures of oyster community metrics with sessile invertebrates exhibited clear trends in Mosquito Lagoon. Species richness and the density differed temporally, because of the month of sampling (ANOVA: $P < 0.001$; Fig. 2, 3; Table 3, Table 4). Richness was significantly higher during June, July, August and October ($P < 0.001$; Fig. 2). Additionally, February had the lowest richness (Fig. 2). Density, the number of organisms per net, was significantly higher in June, July and August of 2004 than all other sampling periods (ANOVA: $P < 0.001$; Fig. 3). Furthermore, spe-

cies richness and density were higher on living oysters in clusters than on single disarticulated oyster shells (ANOVA for both: $P < 0.001$; Tables 3, 4; Fig 4). Species found only on live oysters included mussel *Lithophaga bisulcata*, ascidian *Perophora viridis* and bryozoan *Hippoporina verrilli*. Reef type (reefs with dead margins or reference reefs) did not have a significant influence on the community metrics, species richness ($P = 0.098$) or density ($P = 0.207$) (Tables 3, 4). Site did not have a significant effect on species richness (ANOVA: $P = 0.964$) or density ($P = 0.644$) (Tables 3, 4).

Motile Macrofauna

During this study, 64 motile species were found on oyster reefs in Mosquito Lagoon. Fifty-one species were collected using lift nets (Table 5) and an additional 13 species were observed by researchers elsewhere on reefs and in nearby subtidal waters (Table 2). Chordata was the most abundant phyla found to be

TABLE 2.

Additional macrofauna observed on oyster reefs within Mosquito Lagoon. These species were not collected in the lift nets.

Sessile Species		
Phylum	Species Name	Common Name
Annelida	<i>Polydora websteri</i>	Oyster mud worm
Mollusca	<i>Modiolus americanus</i>	Tulip mussel
	<i>Mercenaria mercenaria</i>	Hard shelled clam
	<i>Anadara transversa</i>	Transverse ark
	<i>Anadara ovalis</i>	Blood ark
	<i>Martesia cuneiformis</i>	Striated wood paddock
	<i>Crepidula convexa</i>	Convex slipper shell
Ectoprocta	<i>Conopeum</i> spp.	Lacy crust bryozoan
	<i>Zoobotryon verticillatum</i>	Moss bryozoan
	<i>Hippoporina verrilli</i>	
Chordata	<i>Molgula manhattensis</i>	Sea grape
	<i>Botrylloides nigrum</i>	Black tunicate
	<i>Botryllus planus</i>	Royal tunicate
	<i>Botrylloides schlosseri</i>	Goldenstar tunicate
	<i>Didemnum</i> sp.	
Motile species		
Phylum	Species Name	Common Name
Arthropoda	<i>Hexapanopeus angustifrons</i>	Narrow mud crab

	<i>Pleuroploca gigantea</i>	Florida horse conch
	<i>Polinices duplicatus</i>	Atlantic moon snail
	<i>Symphurus plagiatus</i>	Blackcheek tonguefish
Chordata		

utilizing the oyster reefs, with 23 fish species found. Mollusca were the second most prevalent phyla, with 20 different species found (Tables 2, 5). Other phyla that were represented in the collections included: Arthropoda (18 species), Echinodermata (2 species) and Annelida (1 species) (Tables 2, 5). The bigclaw snapping shrimp *Alpheus heterochaelis* and the flat mud crab *Eurypanopeus depressus*, dominated the collections numerically year-round (Table 5).

Species richness and density differed because of the month of

TABLE 3.

Four-factor nested ANOVA comparing species richness of sessile organisms in lift nets. Factors were reef type (dead margin or reference; fixed), shell type (live clusters or disarticulated shells) nested within site nested within reef type (random), and month (fixed).

Source	df	Mean Square	F	Significance
Reef type	1	64.201	4.625	0.098
Site (Reef type)	4	13.881	0.133	0.964
Shell type (Site (Reef type))	6	104.321	42.236	<0.001
Month	11	85.401	34.576	<0.001
Residual	697			

TABLE 4.

Four-factor nested ANOVA comparing density of sessile organisms in lift nets. Factors were reef type (dead margin or reference; fixed), shell type (live clusters or disarticulated shells) nested within site nested within reef type (random), and month (fixed).

Source	df	Mean Square	F	Significance
Reef type	1	68406.006	2.265	0.207
Site (Reef type)	4	30195.728	0.657	0.644
Shell type (Site (Reef type))	6	45976.603	16.335	<0.001
Month	11	35020.837	12.443	<0.001
Residual	697			

sampling (ANOVA: both $P < 0.001$; Table 6, Table 7). Richness was higher in November–December, January and May (Fig. 2). Density was significantly higher in June, November and December 2004 than any of the other sampling dates (Fig. 3). Reef type (reefs with dead margins or reference reefs) did not have a significant influence on species richness (ANOVA: $P = 0.985$) or density ($P = 0.624$) (Tables 6, 7). Site did not significantly affect species richness (ANOVA: $P = 0.181$), however it did significantly affect density ($P = 0.002$) (Tables 6, 7).

Environmental Variables

During the 13-mo study, the monthly mean temperatures in Mosquito Lagoon ranged from 16°C to 31°C (Fig. 5a). Salinity ranged from 25–35 ppt (Fig. 5b), falling within the typical average range of 25–45 ppt for the monthly mean in Mosquito Lagoon (Walters et al. 2001). The lowest salinity (25 ppt) occurred immediately after the 2004 hurricane season (Fig. 5b). Total sediment loads differed significantly between sites (ANOVA: $P = 0.011$), but not reef type ($P = 0.234$) (Table 8; Fig. 5c). After sediment loads were separated into fractions, percent silt/clay still did not differ significantly between reef type (ANOVA: $P = 0.454$) or sites ($P = 0.482$) (Table 9; Fig. 5d). During the months of June 2004 and June 2005, both sediment load and percent silt/clay differed temporally (ANOVA: $P = 0.004$ and <0.001 , respectively). Tukey results showed sediment loads to peak in June 2004,

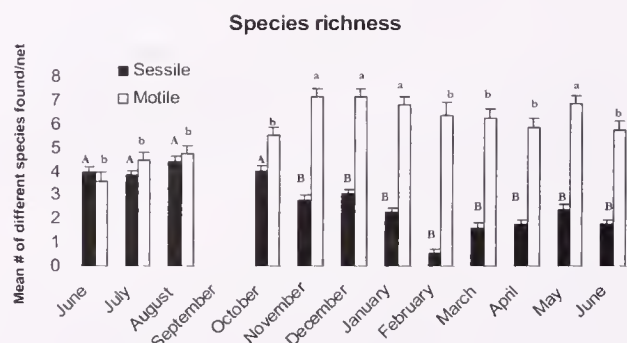

Figure 2. Monthly mean richness (total number of species) \pm SE per net per month from June 2004 to June 2005. September data are missing because of 2004 hurricane activity. When compared with ANOVA and a Tukey-Kramer *post-hoc* test, significantly higher months are depicted by A versus B for sessile species and a versus b for motile species.

Figure 3. Monthly mean density (number of individuals) \pm SE per month from June 2004 to June 2005. September data missing because of 2004 hurricane activity. When compared with ANOVA and a Tukey-Kramer *post-hoc* test, significant higher months are depicted by A versus B for sessile species and a versus b for motile species.

whereas percent silt/clay fractions were highest in June and July 2004, and January 2005 (Fig. 5c, 5d).

DISCUSSION

The assemblage of macrofauna associated with the intertidal oyster reefs during our lift net study was similar to those previously reported on oyster reefs in the southeastern United States (sessile species: Wells 1961; motile species: Meyer 1994, Breitburg 1999, Coen et al. 1999, Posey et al. 1999, Glancy et al. 2003,

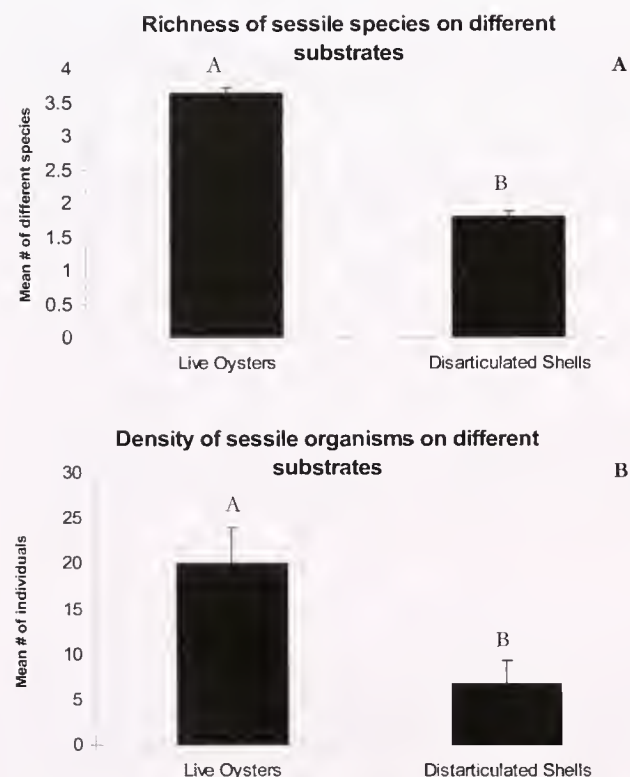

Figure 4. (a) Mean richness (\pm SE) of sessile organisms on live oysters compared with disarticulated shells. (b) Mean density (\pm SE) of sessile organisms on live oysters compared with disarticulated shells. Significant differences are depicted by A versus B.

Tolley et al. 2005, Tolley & Votely 2005). Our data also support earlier research conducted in the Indian River Lagoon system that looked at the sessile species diversity on hard substrata, although not specifically associated with *Crassostrea virginica* (Mook 1976, 1980, 1981 and 1983). As is typical for shellfish assemblages (O'Beirn et al. 2004), the oyster reef community within Mosquito Lagoon was dominated (in terms of abundance) by only a few taxa (i.e., Annelida, Arthropoda and Chordata) (Table 1 and 5).

Sessile Macrofauna

The most abundant sessile species in the nets were in the genus *Balanus*. These organisms were present year-round on oyster reefs and numerically dominant in all nets. *Balanus eburneus*, the native ivory barnacle recruited to shells placed in lift nets during each month of our survey (Table 1). Monthly recruitment ranged from 87 recruits in February 2005 to 2,447 in July 2004. In fact, every net always had at least one *B. eburneus*. *Balanus amphitrite*, the purple striped barnacle, invaded the IRL approximately 100 y ago (J. Carlton pers. comm.). It was common but not as abundant as its congener (Table 1). Numbers of *B. amphitrite* decreased dramatically during the colder months of the year (Table 1). The abundance of these barnacles in this system outcompeting *C. virginica* for space may be associated with declines in oyster populations in Mosquito Lagoon (Boudreaux 2005). Dense sets of *Balanus* spp. monopolizing all free space on oyster reefs suggest intense spatial competition between oysters and barnacles in the IRL during summer and fall months (Boudreaux 2005).

The nonnative bivalve mussel, *Mytella charruana*, was found during this study (Boudreaux & Walters 2006). This South American bivalve was first found in lift nets in August 2004 and has since rapidly spread within northern Mosquito Lagoon (Boudreaux & Walters 2006). Although low numbers of this species may have predated our study, no individuals were recorded in a 3-y study in these waters between 1998 to 2001 (L. Walters unpublished data).

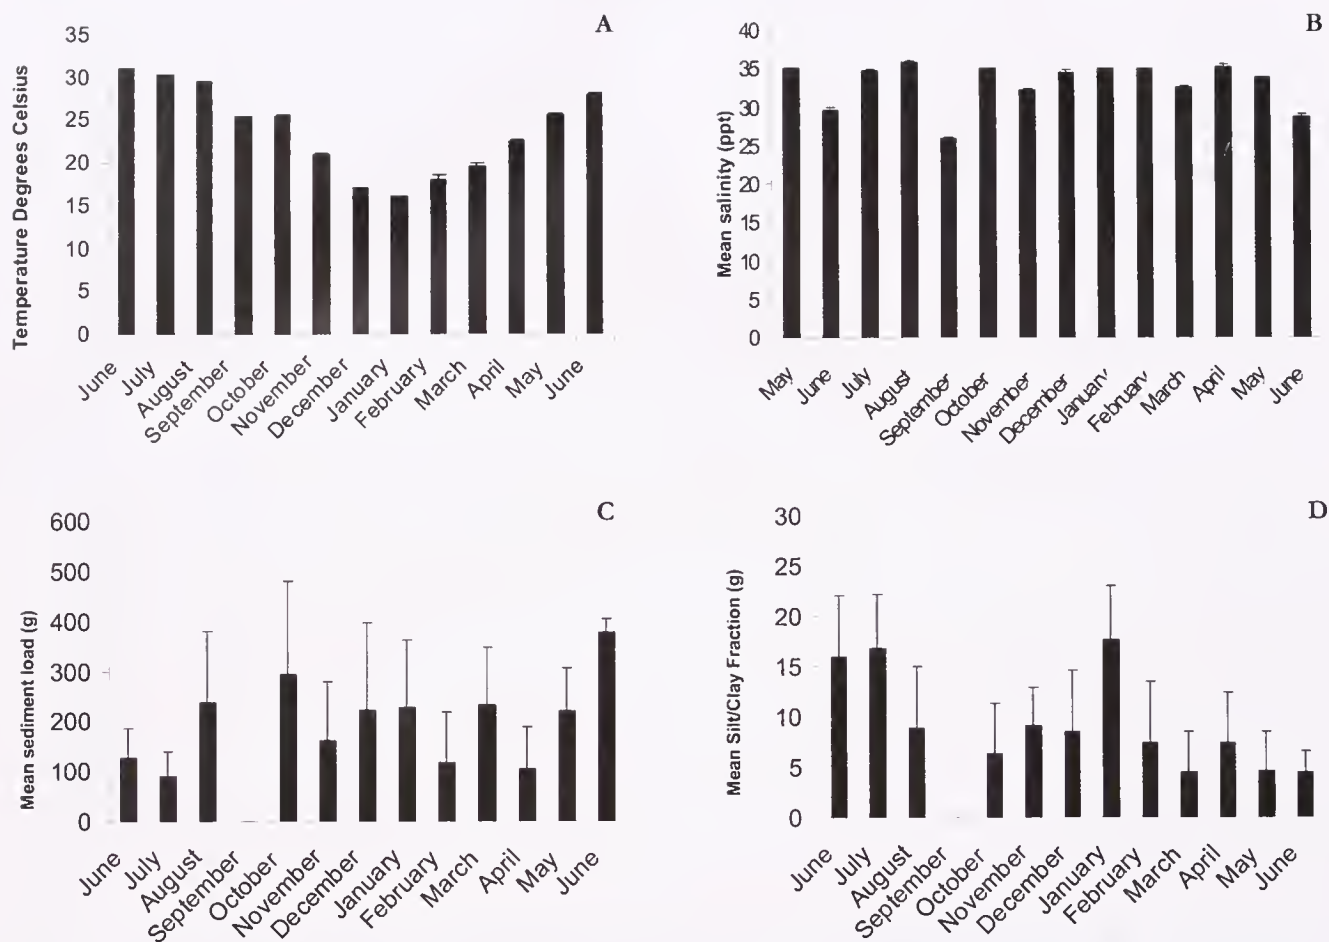

Figure 5. Abiotic variables (a). Mean monthly temperatures (\pm SE) at lift net sampling dates in Mosquito Lagoon. (b) Mean salinities (\pm SE) of Mosquito Lagoon on lift net sampling dates. (c) Mean sediment load (\pm SE) per month from June 2004 to June 2005. (d) Mean silt/clay percentage (\pm SE) per month from June 2004 to June 2005.

One individual of the invasive Asian green mussel *Perna viridis*, which has devastated some oyster reefs in Tampa Bay, Florida (Baker et al. 2003), was also recently found on a piling in Mosquito Lagoon (MB pers. obs.). It has not been found on Mosquito Lagoon oyster reefs to date. Both nonnative bivalves continue to be monitored within the IRL.

Motile Macrofauna

The two most abundant motile species sampled within the lift nets were the bigclaw snapping shrimp *Alpheus heterochaelis*

(2,489 individuals) and the flat mud crab *Eurypanopeus depressus* (1,217 individuals) (Table 5). Previous studies found these two species to be present in temperate waters on both the Atlantic coast of North Carolina (132 individuals of *E. depressus*; Glancy et al. 2003) and the gulf coast of Florida (3,184 individuals of *E. depressus*, 364 individuals of *A. heterochaelis*; Meyer 1994). Similar to Tolley et al. (2005), we found the replacement of temperate species by tropical congeners, including the replacement of the striped blenny *Chasmodes bosquianus* in the Northern Atlantic (Breitburg 1999, Coen et al. 1999) by the Florida blenny *Chasmodes saburrae*.

The fifth most abundant mobile species was the green porcelain crab, *Petrolisthes armatus* (Table 5). It is considered an invasive exotic along the South Atlantic Bight (Knott et al. 1999, Glancy et al. 2003). Populations of this species can historically be found in the Pacific (i.e., California to Peru) and the Atlantic (i.e., Africa, Ascension Island, Bermuda, Bahamas, Gulf of Mexico, West Indies, Caribbean and South America down to Brazil; Knott et al. 1999). Although the pathway of introduction remains unknown, ballast transport and increasing winter temperatures, which favor its establishment are possibilities (Knott et al. 1999). It was first collected along Florida's east coast in the 1930s in Biscayne Bay and Miami Beach (Knott et al. 1999). Slowly, it spread northward, becoming well established in the Indian River Lagoon system (Knott et al. 1999). Studies have shown abundances to increase dramatically in only a few years after introduction (Knott et al. 1999). The current range of *P. armatus* along the South Atlantic Bight stretches from South Carolina down to the southern tip of Florida (Knott et al. 1999).

Size and biomass data for several crustacean and fish species revealed that both juvenile and adult individuals were present on the reefs (Table 5). For example, large ranges were seen for the big-claw snapping shrimp *Alpheus heterochaelis* (length 1.6–2.5 cm; biomass 0.3–0.5 g), blue crab *Callinectes sapidus* (length 2.3–4.3 cm; biomass 1.5–6.6 g), stone crab *Menippe mercenaria* (length 1.0–2.1 cm; biomass 1.7–3.3 g), grass shrimp *Palaemonetes vulgaris* (length 2.5–3.8 cm, biomass 0.3–0.6 g) and pink shrimp *Penaeus duorarum* (length 2.8–6.5 cm, biomass 0.3–2.4 g) (Table 5). Within the Chordata family, different life stages were seen for the sheepshead *Archosargus probatocephalus* (length 4.4–9.7 cm, biomass 8.5–19.8 g), pinfish *Lagodon rhomboides* (length 2.3–7.7 cm, biomass 0.1–8.3), gray snapper *Lutjanus griseus* (length 3.0–11.2 cm, biomass 0.6–21.3 g), oyster toadfish *Opsanus tau* (length 2.3–9.0 cm; biomass 0.2–13.3 g), and numerous killifish and goby species (Table 5).

The blue crab *Callinectes sapidus*, the pink shrimp *Penaeus duorarum* and juvenile forms of several important finfish species were collected in the lift nets within Mosquito Lagoon (Table 5). Hence, commercially and recreationally valuable species are utilizing oyster reefs within Mosquito Lagoon, confirming the importance of oyster reefs to the economy of this region. These species were also found to be utilizing oyster reefs on the west coast of Florida (Tolley et al. 2005).

Additional comparisons can be made with the motile species found on oyster reefs in Mosquito Lagoon to lift net studies of intertidal reefs on the west coast of Florida (26° 25'56"N, 81°48'34"W) (Tolley et al. 2005, Tolley & Volety 2005). Salinities and temperatures found in Mosquito Lagoon (mean: 33 ppt, 23.8°C) are comparable to the system studied in southwest Florida (mean: 32.5 ppt, 27.1°C). Overall species richness (the total number of species found per net) was found to be similar between the two different Florida locations (Gulf: 4–11 species/month versus Mosquito Lagoon: 4–11 species/month), whereas density was slightly lower in Mosquito Lagoon (Gulf: 20–400 organisms/net versus Mosquito Lagoon: 12–40 organisms/net). In both systems, there were more fishes than decapod crustacean species (Gulf: 16 versus 9, Mosquito Lagoon: 23 versus 18). In both locations, decapod crustaceans dominated all motile samples numerically.

Dead Margins Affect on Oyster Reef Communities

Dead margins, attributed to wakes from recreational boating in Mosquito Lagoon (Grizzle et al. 2002, Wall et al. 2005), did not

have a significant effect on the back-reef usage of oysters as substrate by either sessile or motile species (Tables 3, 4, 6 and 7). The back-reef areas of both were also visually very similar. This suggests the back-reef areas on oyster reefs with dead margins function similarly to a reference oyster reef with no dead margin.

Although dead margins did not have an impact on richness or density of organisms found, sessile organisms preferred to settle on living oyster clumps rather than on the disarticulated shells placed within the nets (Fig. 4). The 3-dimensional structure of the two settlement substrates was very different. Disarticulated shells were single and loose, laid flat on the benthos, and were often covered by sediment. These shells were frequently displaced by water motion. Live oysters attached together to form clusters and rarely moved. These 3-dimensional clusters probably provided more protection and refuge from predators for sessile inhabitants than the 2-dimensional, disarticulated shells. Subsequent research has shown that reference reefs contained twice more oyster clumps than reefs with dead margins within Mosquito Lagoon (Stiner 2006). Combined, these results reveal a new negative impact of dead margins on sustaining biodiversity in Mosquito Lagoon.

Wall et al. (2005) found an increase in sediment accumulation on the seaward edges (fore-reef areas) of reefs with dead margins in Mosquito Lagoon and suggested this was caused by sediment resuspension associated with large numbers of boat wakes. Increased sediment has been shown to decrease the settlement of *Crassostrea virginica* (Boudreaux 2005). Thus, any difference in sediment loads between locations would have been predicted to have an effect on species assemblages between the two types of reefs (reference and dead margins). However, this study focused exclusively on the back-reef regions of oyster reefs and did not show any differences in sediment loads between reef types. Dead margins are hypothesized to protect these back-reef areas by preventing sediment accumulation.

During this study we documented the usage of intertidal oyster reefs in Mosquito Lagoon by 105 different species. This included 76 invertebrates and 29 chordates. The richness in diversity found within the reefs of *Crassostrea virginica* is comparable with other systems in the Indian River Lagoon system. A study of decapods associated with seagrass communities in the Indian River Lagoon showed remarkable diversity. In all, 38 decapod species were found in seagrass beds (Gore et al. 1981; Smithsonian Institution 2006) as compared with the 19 decapod species we found using oyster reefs (Tables 2 and 5). These examples demonstrate the extremely high diversity in the IRL that can be attributed to its important habitats, including seagrass beds and oyster reefs. The data from this study are an important step to gaining a better understanding of these oyster reefs and their essential role in the estuary. Additionally, this data provides a baseline from which to evaluate efforts to practice sustainable ecosystem management of *Crassostrea virginica* within Mosquito Lagoon.

ACKNOWLEDGMENTS

The authors thank the University of Central Florida and Canaveral National Seashore for their support in this project. Funding was provided by the University of Central Florida Biology Department, including Research Enhancement Grants (MB, JS), as well as the Aylesworth Foundation (JS), Sigma Xi Grant in Aid of Research (MB), and Florida Sea Grant (LW). We greatly appreciate all those who helped with data collection: M. Black, M.

ABSTRACT The Eastern oyster (*Crassostrea virginica*) is an economically important fisheries resource along the US Gulf Coast and the eastern seaboard. In the past few years, Mississippi has ranked second in the country in shellfish production, harvesting an average of 350,000 sacks (~15.8 million kg of oysters) per year. A GIS-based decision support tool was developed to aid the Mississippi Department of Marine Resources in managing shellfish in the state. The tool was designed using the ESRI ArcGIS 8.3 Arcview software, which enabled us to integrate GIS data layers (e.g., oyster reef sites) with a program that automatically obtains Pearl River stage (gage height) and rainfall amount data from the USGS and NOAA websites, respectively. The program then compares the data with established area-specific standards and makes recommendations to the shellfish manager on the area(s) that should be closed or opened. The decision support tool is the first tool developed for shellfish management in the US Gulf Coast area. Although it was developed for use in Mississippi, it can be modified for use in other states. It simplifies the shellfish management process and maintains a database of the water quality data and the management actions that have been taken, thereby facilitating data analyses and preparation of reports.

KEY WORDS: oyster management, Mississippi Sound, river stage, precipitation, GIS data layers

INTRODUCTION

The Eastern oyster (*Crassostrea virginica*, Gmelin 1791) is one of the economically important fisheries resources in the eastern seaboard of the United States and the US Gulf Coast region, and it accounts for more than 60% of all oysters harvested in the United States (Gore 1992). In the past few years, Mississippi has ranked second in the country in shellfish production, and harvested an average of 350,000 sacks (~15.8 million kg of oysters) per year.

Crassostrea virginica inhabits shallow waters in intertidal and subtidal zones, and their survival and production depend chiefly on phytoplankton productivity, flooding, salinity and temperature variations, levels of parasitism by *Perkinsus marinus* (dermo) and *Haplosporidium nelsoni* (MSX) and predators (Andrews et al. 1959, Menzel et al. 1957, Soniat et al. 1989, Powell et al. 1995, Jordan 1995). Although *C. virginica* tolerates a wide range of salinity with lower and upper limits of about 2 ppt and 39 ppt, respectively (Shumway 1996), high salinities and warm temperatures are conditions that favor the major predators and parasites of the shellfish. For example, the conch, *Strombula haemastoma* thrives at salinities >12 ppt and can have significant predatory impacts on the oyster population (Butler 1954, Gagliano et al. 1970). Another major cause of mortality of oysters in high salinity areas and during warm months along the Gulf of Mexico is *P. marinus*, a parasitic protozoan (Ogle & Flurry 1980, Ray 1996, Soniat 1996). The impacts of *P. marinus* parasite on oysters depend on local as well as regional variations in climatic factors (Powell et al. 1992, Kim & Powell 1998).

Management of shellfish is aimed at enhancing the habitat via cultch planting and cultivation, harvest control, and minimizing the risks to humans of consuming raw contaminated shellfish. Disease outbreaks resulting from the consumption of oysters contaminated by bacterial (e.g., *Vibrio vulnificus* and *Vibrio parahaemolyticus*) and viral pathogens (Leonard 2001, see also a review by Rose et al. 2001) have been reported in other states. The levels of these pathogens depend on climatic factors such as water temperature, intensity of solar radiation and precipitation. The latter is usually accompanied by runoff carrying pollutants into coastal waters (Lipp et al. 2001). To reduce the risks of acquiring diseases caused by consumption of contaminated oysters, the United States Food and Drug Administration and the Interstate Shellfish Sanitation Conference (ISSC) formed the National Shellfish Sanitation Program (NSSP) that developed criteria for the protection of shellfish harvesting waters (ISSC et al. 1999). For example, the Mississippi Ordinance 1.016 section 15.4.1.3, requires a shellfish harvesting area to be closed "when the geometric mean of the seawater from compliant sampling stations in the area exceed a fecal coliform most probable number (MPN) of 14 per 100 mL and/or more than 10% of the samples exceed a MPN of 43 for a 5-tube 3 dilution test."

In Mississippi, rainfall amounts and/or Pearl River stage are used as metrics for closing shellfish harvesting areas in Mississippi Sound. Many years of studies indicate that both factors are highly correlated with fecal coliform levels (Chigbu et al. 2004a). Each of the nine conditionally approved shellfish harvesting areas in Mississippi has specific closure criteria. These are monitored by designated MDMR personnel using sources such as telephone, various official reports, internet, as well as by direct observation, as stated in the Ordinance 1.016. The objective of our study is to design a GIS-based decision support tool that will ease the process of shellfish management in the state. Although GIS-based tools and meth-

ods have been developed for various projects including, microbial risk assessments (Kistemann et al. 2001a, 2001b), environmental impact assessments (Gustafson et al. 2001, Sahin & Kurum 2002), flood area and damage estimation (Renyi & Nan 2002) and resource management (Webb & Bacon 1999), to our knowledge none is available for use in shellfish management in the US Gulf Coast region.

Study Area

Mississippi Sound has a mean depth at midtide level of 3 m, and is partially separated from the northern Gulf of Mexico by a number of barrier Islands. Within the estuary, water from the Gulf mixes with water that flows in from a number of bayous and rivers. The Pearl and Pascagoula Rivers account for more than 90% of freshwater discharge into the Sound (Eleuterius 1978). The Mobile and Mississippi Rivers sometimes contribute significant freshwater into the eastern and western portions of the Sound, respectively (Orlando et al. 1993). The eastern and western parts of the Sound have more variable and lower salinities than the central part of the Sound. Under most conditions, Mississippi Sound is partially or well mixed because of tidal action and winds (Eleuterius 1978).

Pearl River is about 789 km long and drains an area of approximately 23,000 km² before emptying into the western part of the Mississippi Sound, an area that contains some of the most productive oyster populations in the Southeastern United States (Gore 1992). Studies conducted from June 1973 to February 1975 (Eleuterius 1977) suggested that the area experiences bottom minimum and maximum salinity of 2.0–4.0 ppt and 18.0–22.0 ppt, respectively.

Oyster Management in Mississippi Sound

The Department of Marine Resources manages about 17 natural oyster reefs in Mississippi. About 97% of the harvested oysters in Mississippi come from the reefs in the western part of the Mississippi Sound. Management of the Sound for shellfish harvesting is currently based on Pearl River stage, local rainfall amounts and fecal coliform counts (Table 1). River Stage information is collected directly from the USGS website for specific river gauges. The National Weather Service web-site is monitored for rainfall from three NOAA rain gauge locations: Bay St. Louis, Waveland and Pascagoula, MS.

Historical data on fecal coliform levels during the oyster-harvesting season (typically October to April), have been used by shellfish managers to classify Mississippi Sound into areas desig-

nated as Approved, Conditionally Approved, Prohibited, Restricted or Unclassified. Harvesting of oysters for direct consumption is permitted only in areas designated as approved or conditionally approved. At present, nine areas are designated as conditionally approved, each of which has specific opening and closing criteria (Table 1), based on rainfall amounts and/or river stage as outlined in the Mississippi Ordinance 1.016. Beside heavy precipitation, other factors listed in the Ordinance that may result in temporary closures of an approved or conditionally approved area include "a hurricane, flooding, chemical spill, hazardous waste or raw sewage discharge, sinking or grounding of vessels carrying hazardous cargoes, evidence of the existence of marine biotoxins."

METHODS

The GIS data layers that were used in the tool included the oyster reefs, shellfish management areas, sampling stations for water quality monitoring, Gulf Coast imagery, and the USGS river gauge locations. The tool was designed using the Environmental Systems Research Institute (ESRI) ArcGIS 8.3 Arcview and Microsoft Access. The ESRI package provides the user the capability to use geographic data, as well as a programming environment that integrates Visual Basic for application and the ArcObjects library. Microsoft acts as an external relational database that is used to store the metrics for each of the oyster zones as well as the current and historical gauge measurement and information data. The tool automatically obtains river gauge information from the USGS website: <http://waterdata.gov>, and the National Weather Service (NWS) precipitation data from the NOAA website: <http://www.srh.noaa.gov>. Because the gauge data are ingested from the various websites, they are parsed and stored in the corresponding table in the backend database. On a predetermined time interval, the application is designed to use the current gauge data to decide whether an area should be closed, and then uses data on fecal coliform counts to determine whether the area should be reopened. The fecal coliform information is stored in a separate Access database. The readings are stored in a database at a remote laboratory and then transferred to the cataloging database via an automated E-mail application. The tool was built to run on an IBM compatible with Windows 2000 operating system and the following specifications:

- CPU speed of 450 MHz (minimum); 800 MHz or higher is recommended
- A pentium or higher processor
- Memory/RAM 128 MB (minimum); 256 MB or higher recommended
- Swap space 300 MB (minimum)
- Disk space of 695 MB FAT32 for the ESRI software, and 300 MB for data storage

RESULTS AND DISCUSSION

The shellfish decision support tool consists of 5 major components, namely, the Shellfish Management, Manual Close, External Conditions, Rules Change and Strategic Management, the functions of which are summarized in Table 2. The display user interface for the tool (Fig. 1) is divided into 5 areas.

Area 1 contains the typical user interfaces found in normal office applications such as MSWord, MSeExcel, including "file

TABLE 1.

Criteria for closing conditionally approved shellfish harvesting areas

Area	Closing criteria
Area IB-CA	10 ft Pearl River Stage and/or 2 inches rainfall
Area II A-CA	10 ft Pearl River Stage and/or 1 inch rainfall
Area II B-CA	10 ft Pearl River Stage and/or 1 inch rainfall
Area II C-CA	12.5 ft Pearl River Stage and/or 2 inches rainfall
Area II D-CA	10 ft Pearl River Stage and/or 1 inch rainfall
Area III-CA	2 inches rainfall
Area IV-CA	10 ft Pearl River Stage and/or 1 inch rainfall
Area V-CA	2 inches rainfall
Area VIII-CA	0.75 inches rainfall

TABLE 2.
Main components of the shellfish management tool and their functions

Main components	Functions
1. Shellfish management	<p>*Monitors rainfall and river gauge data and compares it to monthly rule criteria for each area.</p> <p>*Recommends closure of an area when certain criteria have reached the threshold defined in the Shellfish Management Plan.</p> <p>*Allows for fecal coliform counts to be analyzed, and determines when it is safe to re-open an area for oystering.</p>
2. Manual close	<p>*Provides DMR officials with the ability to allow some other closing conditions such as oil spills and hurricanes which are not automatically monitored by the application.</p> <p>*When an area has been manually closed, it can only be manually reopened.</p> <p>*The manual close function prohibits or "locks-out" normal operations of the shellfish management function for the area(s) normally closed.</p>
3. External conditions	<p>*Allows DMR officials to close for other specified reasons, hence it is similar to the Manual close function.</p> <p>*Allows latitude and longitude coordinates to be associated with the closing event.</p>
4. Rules change	<p>*Allows the tool to remain up-to-date with amendments to Ordinance 1.016 by making it possible for DMR officials to change any closing or opening criteria (e.g. river stage levels, rainfall amounts, geometric mean MPN level) for any of the conditionally approved areas.</p>
5. Strategic management	<p>*Used for longer term (e.g., 1 year) evaluation of the shellfish harvesting areas based on fecal coliform counts, in order to determine whether a re-classification of oyster-harvesting areas is necessary.</p>

save, exit, copy and paste." in addition to some ArcInfo 8.2 functionality.

Area 2 contains the graphical user interfaces (GUI) for the Shellfish Management Application. The tool bar has buttons, each of which operates a separate function within the application.

- (a) The Shellfish Management function button continually monitors river stage and precipitation and automatically recommends whether an oyster harvesting area should be closed. The program's recommendations are reviewed by the DMR officials who then decide whether to accept or reject the recommendations.

When the data being monitored by the application indicate a status change to a Shellfish Management area, a Shellfish Management Form (Fig. 2) automatically opens. The form has 5 areas that show Program Recommendations, National Weather Service (NWS) data comprising information on rain gauges at Waveland, Bay Saint Louis

and Pascagoula, MS and the US Geological Survey (USGS) Pearl River stage data at Pearl River, Louisiana. In addition, the form has a time stamp that shows the latest time that the external data from the gauges were collected from external websites by the shellfish application. Finally, the form has an error message display area. If no value is found for rainfall, an error message will notify the user in the area, and if the value is invalid, it will be presented as "-9999" in the table.

When the program recommendations button is selected from the Shellfish Management Form, the program recommendations form opens (Fig. 3) to allow DMR staff to review the reasons why the application is recommending a status change. The application's recommendation can then be accepted or rejected by the DMR staff.

There are 5 areas on the Program Recommendations Form: (1) Area Tabs; (2) Recommendation; (3) Reason for Recommendation; (4) Reason for Rejection and (5) Process Recommendation.

The area tabs consist of nine separate and distinct tabs; each tab contains information specific for a particular area. If the tab heading is in bold, it indicates the particular area has a recommended status change otherwise, no status change recommendation exists.

The recommendation tab has a title that shows either Recommend Open or Recommend Close, which is associated with check boxes for use by DMR staff to indicate an acceptance or rejection of the application's recommendation. The reason for recommendation tab describes why the application is recommending a change for the area. The reason for rejection tab is for use by DMR officials to record their reasons for rejecting a recommendation made by the tool. The reason will be stored in the database and can be reviewed by the current status or history reports functions. The process recommendation tab is selected to update the display with the current status (whether accepted or rejected). If a status change was recommended and this button is not selected, the display will not reflect the status changes. This tab should be selected after all areas have been reviewed and recommendations are either accepted or rejected. The map display will reflect the changes accepted (e.g., Fig. 4). The program "recycles" every four hours when more information is received from the USGS and NWS websites. If an area is not closed, even though the application recommends it, the area will again be recommended to close when the program recycles in four hours.

- (b) The external conditions buttons are used to close and re-open areas for events that are not routinely monitored by the Shellfish Management application. The add external conditions allows an event to be pinpointed on the map with either latitude/longitude coordinates or a mouse-click on the screen. The delete external conditions button removes external conditions, which have been previously established.

When the external conditions buttons are selected, the external conditions form (Fig. 5) opens. This form consists of nine areas: (1) Event Location; (2) Area Name and Present Status; (3) Date/Time; (4) Latitude/Longitude; (5) New Status; (6) Open/Close All Zones; (7) External Condition; (8) Operator Comments and (9) Set Status.

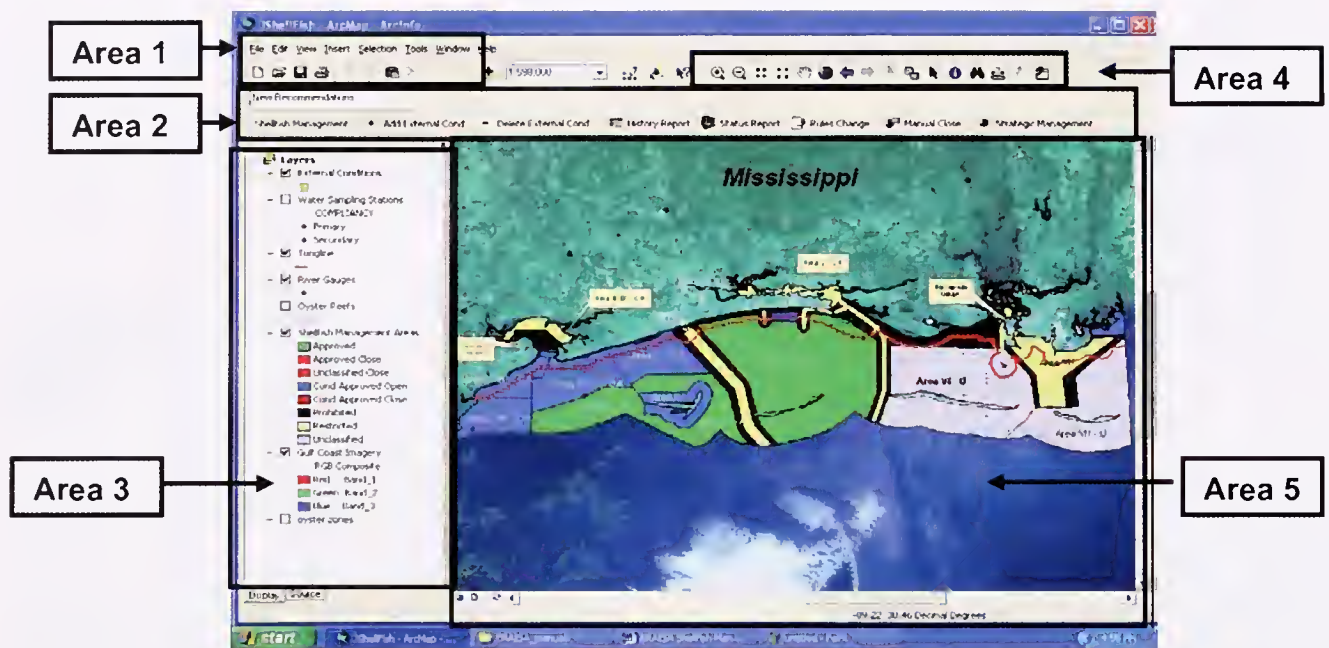

Figure 1. The display user interface for the Shellfish Management Tool

The event location button allows one to identify the location of an event by selecting entered mouse click or entered by coordinate value. The area name and present status button lists all of the areas and their present statuses. The area(s) can be selected by left-clicking the mouse. To select more than one area, hold down the shift key while

selecting the area with the mouse. Areas that are selected are highlighted.

The date and time stamp is used to record the time and date that the manual close function is used. This is recorded for the current status and history reports.

The longitude and latitude buttons are used to display

Figure 2. The Shellfish Management Form

The diagram illustrates the 'Program Recommendations' form interface. It features a tabbed structure with tabs labeled 'Area I B', 'Area II A', 'Area II B', 'Area II C', 'Area II D', 'Area III', 'Area IV', 'Area V', 'Area VI', and 'Area VII'. The 'Area I B' tab is active, showing a 'Recommend Close' button, 'Accept Recommendation' and 'Reject Recommendation' checkboxes, and two text input fields: 'Reason for Recommendation' (containing 'Pearl River Gauge (02492600) Flood Value 19.98 feet on 5/5/2003 6:30:00 AM is over the 10 Feet feet limit') and 'Reason for Rejection'. A 'Process Recommendation' button is located at the bottom. Callout boxes point to the 'Recommendation' (the 'Recommend Close' button), 'Reason for Recommendation' (the top text field), 'Reason for Rejection' (the bottom text field), and 'Process Recommendation' (the bottom button).

the longitude and latitude of where the external conditions symbol is on the map display.

The new status button allows the selection of an open or close status of the areas selected in the area names window. Selection is made by clicking on the arrow, which prompts a drop-down menu with Open and Closed to open.

The Open/Close all zones button allows one to select and close or open all areas in the area names list.

The External Condition button allows for the selection of the type of external condition that has warranted closure of an area.

The Operator Comments area is provided to allow additional comments to be noted. These comments are retained for the report features.

The Set Status button is clicked after all the external conditions have been established to process the decision.

- (c) The history report button allows DMR to generate reports of the opening and closing events that have taken place for a particular area, including the reasons for change in status.
- (d) The status report button generates a visual and/or a printed

report for the current status of each of the shellfish harvesting areas.

- (e) The rules change button allows the monthly rule tables to be changed for any of the shellfish harvesting areas. Rainfall amount, river gauge levels, fecal coliform counts, and the values that determine river crest and river rise can be changed using this function.

When the rules change button is selected, the rules change form (Fig. 6) will open and is used to change the criteria for each shellfish management area to open or close, when approved by the authorized person at DMR. There are 6 areas on the form: (1) Select Area ID; (2) Area Information (for area ID); (3) River Gauge Information; (4) Rain Gauge Information; (5) Area Information (for river crest and rise) and (6) Form Navigation. The rules change function is password protected.

The select area ID allows one to select the area that requires a change in its rule criteria. The area information shows the area ID and the seasonal condition rule (area classification status).

Figure 6. The Shellfish Management Rules Change Form.

The river gauge information gives information about the river gauge, such as the agency that it belongs to, as well as the ID, name, and the measurement units. It also has the limit box used to set the maximum height of the river allowed before closing a shellfish area, and the period box

used to set the maximum time (in hours). In Figure 6, for example, Area IIC-CA is recommended to close when the Pearl River gauge reaches 12.5 ft.

The rain gauge information gives details about the rain gauge, such as agency, ID and name and measurement

units. The limit box within the rain gauge information area is used to set the maximum amount of rain (in inches) allowed before closing a shellfish area. The period box is used to set the maximum time (in hours) of rain accumulation. For example, in Figure 6, Area IIC-CA is recommended to close when the Waveland rain gauge shows that it has rained 2 inches in the last 24 h period.

The area information section displays the values the application uses for river crest and rerise. In addition, the maximum acceptable geometric mean fecal coliform count is set here. The crest value change is used to determine when the application considers a river crest has occurred. It considers the river to have crested if the level has dropped 0.04 ft below the highest river value recorded since closure. The ReRise value is used to set the application's river's rerise condition. The river is considered to have reached a level of "re-rise" (which could indicate a condition to close the area again) if the river stage is 0.15 ft above the level that caused the closure. The acceptable geometric mean area is used to set the maximum value for fecal coliform count allowed to keep a shellfish management area open for harvesting.

The navigation area allows the operator to navigate through the rules change records by clicking on the previous and next buttons on the bottom of the form.

- (f) The manual close button, like the external condition function, allows the program to be operated outside of the scope of the shellfish management rules closure recommendations. The rules closure criteria affect only the conditionally approved areas. In contrast, the manual close function allows any area to be closed.
- (g) The strategic management button allows for a year-end evaluation of the shellfish harvesting areas, based on calculations of the geometric means of fecal coliform counts. Fecal coliform data of water samples from each area are used by the application to calculate the geometric mean of the fecal coliforms for each water sample station. These results can then be used by DMR to reclassify areas as approved or conditionally approved. An area can be classified as approved "if the bacteriological quality of the water of every sampling station does not exceed a fecal coliform median or geometric mean MPN of 14 per 100 mL, and not more than 10% of the samples exceed an MPN of 43 for a 5-tube 3 dilution test" as presented in the ordinance. An area may be classified as conditionally approved if the area meets approved area standards under certain conditions specified in the areas management plan (e.g., rainfall or river stage at a particular location is less than the maximum allowed for in the management plan).

Area 3 is known as the table of contents, and shows what layers are active in the map display area.

Area 4 consists of tools used to move around the map display area.

Area 5 is the map display area, where the shellfish management areas are displayed. They will be color-coded as to their status.

Fecal coliform reports are used mainly for two reasons with regard to the shellfish management areas. First, recent fecal coliform counts are used in determining whether the shellfish harvesting areas can be reopened after a rise in river stage and/or a rain event. Second, the strategic management function of the application will evaluate all of the fecal coliform counts for an entire

season. The counts are then computed and used to re-evaluate if the shellfish management area should be classified as approved or conditionally approved. DMR collects water samples from various stations, which are then analyzed for fecal coliforms at the US FDA approved Gulf Coast Research Laboratory, Ocean Springs, Mississippi. The fecal coliform data are sent to DMR via e-mail. The shellfish management application was designed to perform a semiautomatic ingestion of the newly delivered data into the DMR database and also calculate the geometric mean fecal coliform counts to recommend whether to reopen the reefs.

The Pearl River has much influence on the water quality in the western part of the Mississippi Sound, hence Pearl River stage along with rainfall amount are two important variables that the shellfish management tool monitors for closing shellfish harvesting areas. Pearl River stage varies seasonally (Chigbu et al. 2005a), with a peak in late winter/early spring and a minimum in summer/early fall. The river stage also varies between years because of the influence of ENSO events on precipitation (Chigbu et al. 2004). Both seasonal and interannual variations in Pearl River stage are accompanied by increased levels of fecal coliforms, which in turn determine the duration that the conditionally approved shellfish harvesting areas are opened for shellfish harvesting. In fact, Pearl River stage explains as much as 90% of the variations in fecal coliform concentrations in the western part of the Sound (Chigbu et al. 2004).

Fecal coliform levels often peak in water after rain events. In Mississippi Sound, fecal coliform levels peak within 48 h of a major local rain event (>0.5 inches), whereas Pearl River stage typically crests within about 96 h of a rain event (Chigbu et al. 2005b). It is therefore, reasonable to use the total amount of rainfall within a period of 24 consecutive hours for determining whether an area should be closed in the shellfish management tool.

To our knowledge this is the first decision support tool developed for shellfish management in the US Gulf coast area. Although it was developed for use in Mississippi, it can be easily modified for use in other states. It is easy to use; it simplifies the process of closing and opening of the conditionally approved shellfish harvesting areas, and it maintains a time series database of the water quality on which closing and opening of reefs are based as well as management actions that have been taken. It thus facilitates data analysis and preparation of reports. The tool was installed and successfully tested at DMR during the 2003/2004 shellfish harvesting season. Plans are underway to adapt the tool for use in other states.

CONSUMER EVALUATION OF DIPLOID AND TRIPLOID PACIFIC OYSTERS SUBJECTED TO HIGH PRESSURE TREATMENT

J. A. NELL,¹* P. J. O'RIORDAN² AND D. M. OGBURN¹

¹NSW Department of Primary Industries, Port Stephens Fisheries Centre, Taylors Beach NSW 2316, Australia; ²Food Quality (Measurement & Perception) Stream, Food Science Australia, PO Box 52, North Ryde NSW 1670, Australia

ABSTRACT A sample of Australian oyster consumers evaluated the sensory quality of diploid and triploid Pacific oysters subjected to high pressure (HP) treatment with and without salt. Triploid and diploid oysters received comparable hedonic ratings despite having dissimilar condition indices at the time of testing. The HP treatment did not adversely affect the sensory quality of Pacific oysters because the test products received similar ratings of sensory quality to the control (unprocessed) products. Moreover, oysters subject to HP received higher ratings for liking of appearance and were judged to have lower levels of perceived saltiness compared with the control. The use of HP in extending the shelf life of farmed Australian oysters should be investigated.

KEYWORDS: Pacific oyster, high pressure, triploid, consumer sensory evaluation, sensory quality, *Crassostrea gigas*

INTRODUCTION

Commercial production of triploid Pacific oysters *Crassostrea gigas* on the West Coast of North America began in 1985 and now accounts for over 30% of all Pacific oysters farmed there (Nell 2002). The very low fecundity of both chemically induced and natural triploids (Guo & Allen 1994, Gong et al. 2004) make them attractive in areas such as Port Stephens, New South Wales (NSW), Australia, where excessive overcatch makes oyster farming difficult (Nell, 1993). Therefore, because of their potential to reduce overcatch and increase growth rates, the benefits of farming triploid Pacific oysters in Port Stephens was evaluated from February 2002 to February 2004. Live Pacific oysters have a typical shelf life of 7–10 days, when refrigerated at around 4°C, whereas live Sydney rock oysters *Saccostrea glomerata*, have a shelf life of 2–3 wk, when kept cool at 8°C to 15°C (Nell, 2001). Therefore, increasing refrigerated shelf-life of shucked Pacific oysters (Calik et al. 2002), would assist the marketability of this product.

High Pressure (HP) treatment is capable of inactivating spoilage microorganisms and as a result it is currently being used as an alternative to heat treatment for food preservation. Unlike heat treatment, HP has potential to preserve the original nutrient and sensory quality of liquid and semisolid foods by maintaining covalent bond structure during a treatment that is instantaneous and uniform (Farr 1990, Kelly 2000). Therefore, HP presents a number of potential benefits for the preservation of foods and offers a number of benefits when prolonging the shelf-life of ready-to-eat refrigerated foods (Stewart & Cole 2001). Previous studies in the US have found HP treatment to be a useful tool for shucking oysters, as well as providing an extension in the refrigerated shelf-life of the product (Calik et al. 2002, He et al. 2002). HP has also improved the appearance of oysters (López-Caballero et al. 2000) and treated oysters were believed to be slightly “juicier” (López-Caballero et al. 2000), perhaps because of the increased moisture content of HP treated oysters (Cruz-Romero et al. 2003, 2006). The flavor of HP treated oysters may be enhanced, because of the uptake of salt from the water in which oysters were treated (Hoover et al. 1989).

This study was conducted to determine the influence of HP treatment, with or without the addition of salt, on consumer ap-

preciation (appearance, odor, texture, flavor) of diploid and triploid Pacific oysters. In doing so, the sensory quality of the HP treatments was compared with the quality of the untreated control.

MATERIALS AND METHODS

Oysters

This study was undertaken as part of a farming study conducted by NSW Department of Primary Industries (Nell & Perkins 2005). The triploids were produced by fertilization of eggs from diploids with sperm from tetraploids (Guo et al. 1996). Oysters were grown on an intertidal lease in Cromarty Bay, Port Stephens from May 2002 to October 2003 (Nell & Perkins 2005), where the salinity at harvest was 35‰. The market size for Pacific oysters in NSW is around 80 g (86 mm shell height). Because the triploids grew much faster than the diploids (Nell & Perkins 2005), diploids and triploids could not be matched for size. The average whole weight and shell height for the diploid and triploid oysters were 84 g (88 mm) and 101 g (91 mm), respectively.

Immediately after harvesting, oysters were depurated in flow-through tanks in UV sterilized seawater for 36 h. Oysters were packed in ice and transported by air from Port Stephens to Food Science Australia's (FSA) Werribee Center (Victoria) for taste testing. For ease of operation oysters were pooled for Condition Index (CI) determination. Four representative samples of six oysters of each type (diploid or triploid) were used to estimate the whole oyster weight, dry and wet meat weight and CI of oysters used in the taste test. The meats were dried at 90°C for 48 h then transferred to desiccators to cool before determining final dry weight. CI was calculated using the following formula (Crosby & Gale 1990):

$$CI = \frac{\text{dry meat weight (g)} \times 1000}{\text{cavity volume (g)}} \text{ where: } \\ \text{Cavity volume} = \text{whole weight (g)} - \text{shell weight (g)} \\ \text{(Lawrence \& Scott 1982).}$$

Because triploid oysters may suffer discoloration in summer (Hand & Nell 1999, Nell & Perkins 2005) the consumer taste tests were carried out in spring, before triploid Pacific oysters from Port Stephens suffer this problem.

Experimental Treatments

The experimental treatments were: diploid and triploid untreated controls, HP treated diploid and triploid oysters without salt

*Corresponding author. E-mail: john.nell@dpi.nsw.gov.au

and HP treated diploid and triploid oysters with salt. Prior to HP treatment, oysters were washed, clasped with a rubber band and placed in plastic bags filled with either fresh water or 3% saline solution (NaCl on a weight for volume basis in water). Oysters were HP processed in a 35 L HP processing unit (Quintus Press, Avure Technologies Inc, Kent, WA) for 3 min at 275 Mpa. This process shucked the oysters, but their integrity was maintained with the rubber band. After processing, oysters were stored on ice in a 4°C controlled temperature refrigerator for four days. The untreated (control) oysters were washed and stored as described above until the sensory evaluation session.

Consumer Sensory Evaluation

The consumer sample consisted of 61 regular consumers of oysters between the ages of 20 and 60 y from the Melbourne, Victoria, metropolitan area. The sample was divided into four 10-year age groups, each consisting of approximately equal numbers of male and female respondents. Prior to the test, respondents were briefed on the purpose of the trial and signed a participation consent form. Respondents were then instructed on the use of measurement scales and interstimulus palate cleaners. For the purpose of controlled product evaluation, each respondent was seated in an individual sensory booth. The untreated (control) oysters were shucked immediately prior to evaluation and the rubber band was removed from the HP treated oysters. All oysters were presented to respondents on a bed of ice (approx. 4°C) in plastic odorless disposable containers labeled with 3-digit codes. Respondents were instructed to eat the whole oyster. Test products were evaluated monadically (each respondent sees and evaluates only one product at a time in a sequential manner), and order of product presentation was balanced according to a row-column design. Hedonic (pleasure related) appraisal of odor, appearance, flavor, saltiness, texture and overall liking was rated on a 10-cm unstructured line scale anchored at 0 and 10 cm with "dislike extremely" and "like extremely," respectively. Diagnostic ratings of saltiness (perceived salt taste intensity) were then measured using an unstructured line scale anchored at 0 and 10 cm with "not all salty" and "extremely salty," respectively. Finally, respondents rated their "ideal" level of saltiness on an unstructured line scale anchored at 0 and 10 cm with "not all salty" and "extremely salty," respec-

tively. All data was recorded and stored using a sensory data acquisition program (Compusense Inc., Guelph, Ont.).

Data Analysis

One-way analysis of variance (ANOVA; SPSS v 14; SPSS Australasia Pty Ltd., North Sydney, NSW) was used to compare individual products ($n = 6$), process treatments ($n = 3$) and oyster ploidy ($n = 2$). Duncan's *post-hoc* test for means separation was used to determine the nature of discrimination between individual products and between treatments based on significant sensory and affective information. Mean CI values were also compared using one-way ANOVA. Data are expressed as means \pm SD throughout the text. Statistical significance (i.e., differences between products) was established at $P < 0.05$.

RESULTS

Individual Products

Mean hedonic and diagnostic sensory attribute ratings for individual products are outlined in Table 1. There was large variation between individual consumer responses as reflected by the magnitude of the SD (Table 1). No differences were identified between individual products for consumer appreciation of odor, flavor, texture, aftertaste or overall liking. The triploid untreated oysters received a lower rating for appearance ($F [5357] = 6.67; P < 0.01$) compared with the untreated and HP treated diploid oysters. Furthermore, the appearance of the triploid HP treated oysters was rated lower ($F [5357] = 6.67; P < 0.01$) than that of the HP treated diploid oysters. Consumers preferred the saltiness [$F (5357) = 5.24; P < 0.01$] of the diploid and triploid oysters HP treated without saline compared with the untreated products. Furthermore, consumers preferred the saltiness ($F [5357] = 5.24; P < 0.01$) of the diploid and triploid oysters HP treated with or without saline compared with the untreated triploid oyster. The untreated triploid and diploid oysters were perceived to be saltier ($F [5357] = 11.97; P < 0.01$) than the HP treated triploid and diploid oysters (processed with or without saline).

Processing Treatments

Mean hedonic and diagnostic sensory attributes ratings for processing treatments are outlined in Table 2. There was large varia-

tion between individual consumer responses as reflected by the magnitude of the SD (Table 2). Consumers did not convey differences between processing treatments for appreciation of oyster odor, flavor, texture, aftertaste or overall liking. Consumers rated the appearance of the untreated oysters lower ($F [2360] = 4.10$; $P < 0.05$) than that of the HP treated oysters. Consumers also preferred the saltiness ($F [2360] = 11.93$; $P < 0.01$) of the HP treated oysters compared with the untreated oysters. In terms of actual perceived saltiness intensity, the untreated oysters received higher ratings ($F [2360] = 28.51$; $P < 0.01$) compared with the HP treated oysters.

Oysters Type

Mean hedonic and diagnostic sensory attributes ratings for each type of oyster are outlined in Table 3. There was large variation between individual consumer responses as reflected by the magnitude of the SD (Table 3). Consumers did not discern differences between diploid and triploid oysters for liking of odor, flavor, texture, aftertaste, overall liking or saltiness. Furthermore, there was no difference between oysters for consumer appraisal of per-

TABLE 3.

Hedonic and diagnostic sensory attribute ratings* for oyster type.

* Data are expressed as means ± SD.

ceived saltiness intensity. However, consumers did prefer the appearance of the diploid oysters ($F [1361] = 24.08$; $P < 0.01$). From a physiological perspective, there were differences in whole weight, dry meat weight and CI between the diploid and triploid oysters (Table 4).

DISCUSSION

This study showed similar consumer acceptance measures for triploid and diploid oysters. This finding is in agreement with previous hedonic comparisons of diploid and triploid Pacific oysters by consumer panels (Allen & Downing 1994, Maguire et al. 1994, Chao et al. 2001). Similarly, Korac et al. (1996) found relatively similar consumer acceptance ratings for triploid and diploid Sydney rock oysters. Notwithstanding this, in the present study consumers did prefer the appearance of the diploid oysters despite the processing treatment. It is likely that this was caused by the lower CI of the triploid (CI of 84) compared with the diploid (CI of 133) oysters. Ideally, this study should have been done on oysters of similar meat condition, but this is difficult because the CI of diploids (50–150) fluctuates greatly, whereas that of triploids is more stable (70–110) (Nell & Perkins 2005). The main advantage of triploidy in NSW is faster growth and better meat condition over late spring and early autumn when diploids spawn, outside of the possible midspring to autumn period of gonad discoloration (Nell & Perkins 2005).

HP did not have a negative impact on the eating quality of triploid and diploid oysters. Conversely, HP actually improved the appearance of the triploid and diploid oysters, which is in agreement with previous studies (López-Caballero et al. 2000). HP also seemed to reduce the intensity of perceived saltiness in oysters. This effect was appealing to consumers and measurement of their ideal saltiness intensity was similar to that perceived in the HP treated oysters (Tables 1, 2). HP may have reduced the salt content of the oyster samples because processing took place in an aqueous medium and osmotic movement of salt from the oyster to the processing medium may have occurred. However, the salt ion concentration of the oyster and processing medium was not measured before and after processing. Whereas observations based on perceived saltiness were in contrast with a previous report by Hoover et al. (1989), differences in the levels of oyster saltiness observed in the present study did not impact on measures of overall liking.

HP showed considerable promise as a means of improving the sensory quality (appearance and saltiness) of oysters. HP inactivates microorganisms while maintaining sensory and nutritional qualities (Murchie et al. 2005). Specifically, HP reduces the levels of *Vibrio vulnificus* in oysters but little is known of its effect on human enteric viruses (Murchie et al. 2005). As well as investigating efficacy in reducing the levels of human enteric viruses

TABLE 4.

Physiological measurements* of oyster type.

Physiological Measurements	Oyster Type		Significance
	Diploid	Triploid	
Whole oyster weight (g)	84.2 (7.4)	100.9 (3.0)	$p < 0.01$
Dry meat weight (g)	3.8 (0.5)	2.9 (0.1)	$p < 0.05$
Condition Index	132.8 (15.9)	83.90 (3.4)	$p < 0.001$

* Data are expressed as means ± SD.

(Murchie et al. 2005), future studies should also investigate the potential of HP to extend the shelf life of refrigerated oysters (He et al. 2002). This would have important implications from a marketing perspective in terms of product positioning, market access and distribution. Development of oysters from a marketing perspective is imperative (Liu et al. 2006) because demand for this product is strong (Ruello & Associates 2002, 2005).

ACKNOWLEDGMENTS

The authors thank Mr. Ben Perkins; NSW DPI for the field and laboratory work, Mr. G. Browne, Mr. G. S. Diemar and Mr. S. Lyall, oyster farmers in Port Stephens; for supplying oysters for CI monitoring and Ms. R. Marsh for coordinating the sensory trials at Food Science Australia.

TAQMAN® MGB REAL-TIME PCR APPROACH TO QUANTIFICATION OF *PERKINSUS MARINUS* AND *PERKINSUS* SPP. IN OYSTERS

J. D. GAUTHIER,^{1*} C. R. MILLER,² AND A. E. WILBUR³

¹Center for Marine Science, University of North Carolina Wilmington, 5600 Marvin K. Moss Lane, Wilmington, North Carolina 28409; ²Applied Biosystems Incorporated, Foster City, California, 94404;

³Department of Biology and Marine Biology, University of North Carolina Wilmington, 601 South College Road, Wilmington, North Carolina 28403

TABLE 1.

Primer and probe sequences for PERK and PMAR TaqMan® MGB assays. Probes include a 5' 6-carboxyfluorescein (FAM) reporter and 3' MGB.

Perkinsus spp. (PERK) Assay:

Forward: 5'-TCCGTGAACCAGTAGAAATCTCAAC-3'

Reverse: 5'-GGAAGAAGAGCGACACTGATATGTA-3'

Probe: 5'-CCCTTTGTGCAGTATGC-MGB-3'

Perkinsus marinus (PMAR) Assay:

Forward: 5'-TTGTTAACGCAACTCAATGCTTTGT-3'

Reverse: 5'-AAGCGCACATAACGAACCACC-3'

Probe: 5'-GCTTGAACCTAACTCT-MGB-3'

COVER PHOTO: Shellfish provide more than a food crop in many countries. Shell art is a staple of the global tourist industry—this photo taken at La Ballena Gris in Comondú, Baja California Sur, Mexico. Shells from locally collected and consumed species as well as imported shells were used in these trinkets which were assembled on site. (Photo: S. E. Shumway)
